- 3G:** A third-generation mobile telephone technology associated with the ability to transfer both voice data (a telephone call) and nonvoice data such as downloading information, exchanging e-mail, and instant messaging.
- 802.1(X):** An IEEE standard that defines port-based, network access control to provide authenticated network access for Ethernet networks.
- Blog:** Web log in which virtual community members post comments about a given topic.
- Chat:** A program that enables dynamic (instantaneous) conversations using text messaging.
- Information and Communications Technologies (ICT):** Includes e-mail, instant messaging, video teleconferencing, digital libraries, and databases.
- MUD (and MUDding):** MUD stands for multiple user dimension, multiple user dungeon, or multiple user dialogue. It is a computer program in which users log in to and explore a textual theme, story, pretense, or game using a computerized persona called an "avatar."
- Skype:** A proprietary peer-to-peer protocol used for VoIP communications.
- Spyware:** A broad category of malicious software intended to intercept or take partial control of a computer's operation without the user's informed consent.
- Text Messaging:** A two-way conversation using textual forms of communications over a telecommunications medium.
- Virus:** A self-replicating program (in the classification of malicious software, or malware) that spreads by inserting copies of itself into other executable code or documents; typically used for causing damage to computer files.
- VoIP:** Voice over Internet protocol (also called IP telephony, Internet telephony, and digital phone) is the routing of voice conversations over the Internet or any other IP-based network. Voice data flow over a general-purpose packet-switched network instead of traditional dedicated, circuit-switched voice transmission lines.
- Vonage:** A commercial voice over IP (VoIP) network that provides telephone service via a broadband connection.
- WiMAX:** Acronym for worldwide interoperability for microwave access, a certification mark for products that pass conformity and interoperability tests for the IEEE 802.16 standards.

INTRODUCTION: WHAT IS ONLINE BANKING?

Online banking is the use of the Internet to obtain financial services. Its origins can be found in the early 1980s, when many larger financial institutions began to provide access to some banking services through the telephone. With the spread of the personal computer in the 1980s and the emergence of the World Wide Web, online banking became a reality. At first, banks distributed proprietary software that had to be installed on the customer's computer. However, the proprietary approach is problematic: software had to be written for different operating systems such as Microsoft, Apple, and Linux, and the bank had to address all the issues of difficulty and compatibility that arose for their customers.

Online banking changed significantly in the mid-1990s, when Wells Fargo allowed its customers to access some banking services through the Internet, and Security First Network Bank became the first Internet-only financial institution. As the security and simplicity of use of Web browsers improved, virtually all institutions offering online banking migrated to a system that requires a customer only to have a secure Web browser, regardless of the underlying operating system. Since the Web browser is the primary way by which most individuals interact on the Internet, the adoption of this technology for online banking has served to increase the number of individuals willing to engage in online banking.

Banks serve a useful function in offering payment services to facilitate the exchange of goods and services between two parties. An important component of online banking is the provision of payment services. Banks are involved in the entire supply chain of payment services, from providing payment instruments to clearing and settlement. Indeed, because of legal restrictions in most countries, only chartered and regulated banks can be involved in the final clearing of payments through the Central Bank. However, banks face competition from nonbanks in other elements of the payment supply chain. In particular, nonbanks have been prominent in facilitating Internet payments. A significant example is PayPal, which designed a front end for payment services on the Internet and tied it to flexible back-end processing, which can clear a payment using credit cards, the automated clearinghouse, or other alternatives. The success of PayPal and other nonbank payments providers on the Internet suggests that there are

characteristics of Internet retailing that opened up opportunities for providing online payments that banks have yet to exploit (Paunov and Vickery 2004).

The economic analysis of payment systems differs from that of most goods and services because payment systems are two-sided platforms. As Evans and Schmalensee (2005, 78) note, such "businesses are intermediaries that add value if and only if they can appropriately coordinate the demands of two distinct groups of customers." The implication is that consumers and merchants will use banks for payments only if they are willing to pay some or all of the costs of the transaction. The market price for the payments transaction service is also contingent on the acceptability of this form of payment to the other party (Baxter 1983, 543–4).

In Baxter's analysis, there are four parties to the transaction: a purchaser (P), a merchant (M), the purchaser's bank (P bank), and the merchant's bank (M bank). M and P have a demand for transactional services, and M bank and P bank supply those services. Though it may appear that transactional services are private goods, the aggregate demand for them cannot be found by horizontally summing the individual consumer demands. Though P's marginal valuation of the additional unit of transactional services may differ from M's, the valuations cannot be independent of each other. This is because for every purchaser, there must be a payee. Hence, the marginal valuation of a transaction service by one party is contingent on the acceptability of this form of payment to the other party (Baxter 1983, 543–4). The key point for such markets is that there is a price level that induces the transaction to occur, but also a price structure—the ratio of the price paid by the two parties. Competition for provision of Internet payment services is, in part, a search for a price ratio that determines how the cost of payment services is split between merchants and consumers. Nonbank providers of Internet payment services may be successful because, compared to banks, they have found a better solution to this pricing problem (Federal Reserve Bank of Kansas City 2005).

By definition, online banking would not exist without the Internet. The simplest form of online banking merely provides account information; for example, electronic delivery of statements or transfers between accounts within one institution. Table 1 contains a list of the features of bank Web sites. The transactional features are used by bank customers to replace in-person transactions at a brick-and-mortar bank site. Bill-pay services are very

popular with customers. Customers may pay a variety of bills from utility companies, credit card companies, and most other companies that accept electronic payments. Customers may also make direct payments from their accounts. Electronic bill presentment and payment (EBPP) is a form of bill payment by which bills are presented to a customer online, via either e-mail or a notice in an e-banking account. After presentment, the customer may pay the bill online when convenient. The payment is electronically deducted from the customer's account. Most bank customers can now use the automated clearinghouse (ACH) through the online banking services provided by their financial institution. The advent of electronic check conversion has also eliminated the need to physically transfer pieces of paper. ACH was created in the early 1970s to help reduce the volume of paper checks. In 1974, the regional ACH associations formed the National Automated Clearing House Association (NACHA) to facilitate the nationwide clearing of ACH payments. The system originally relied on magnetic tapes and diskettes to exchange ACH files, which required the physical transport of tapes among the ACH participants. The ACH system can process large volumes of individual payments electronically, and it has become the largest payment system in the country. The Federal Reserve processes approximately 75 percent of all the items handled by ACHs in the United States. There is only one private ACH operator in the United States (www.theclearinghouse.org/home.php). Though developed for recurring credit payments, such as a home mortgage payment, developments in technology have increased the frequency of its use and reduced the

number of transactions that go through ACH. In 1994, the Federal Reserve mandated that all ACH payments would have to be done electronically. This requires that all financial institutions dealing with the Federal Reserve directly must have an electronic link to a mainframe computer or personal computer to participate in the ACH.

Informational features replace the need for the banks to provide paper copies to the customer available at the brick-and-mortar bank site (though banks may do both). The administrative features include access to account information and any software that may be needed to conduct financial services. Finally, the Web site can be a portal to provide links to other Web sites and information (Sullivan 2001).

A special category of Internet-only banks also exists (DeYoung 2001, *The Financial Performance, 2001, Learning-by-Doing*). Unlike traditional banks with a physical brick-and-mortar location, these banks have no physical offices where customers can engage in traditional banking services. One example of an Internet-only bank currently operating is the First Internet Bank of Indiana (www.firstib.com). Though the bank claims a cost advantage because "we don't have a costly branch network to support," lower costs do not necessarily mean higher profits. Internet-only banks likely represent a niche market whose customers would be only the most sophisticated and computer-savvy users who also were not bothered by being unable to visit a physical location (Evans 2004). Though there would be some cost savings from not having physical offices, it is not clear that the Internet-only strategy would be as profitable when compared with an institution that

could offer both traditional and online banking (DeYoung 2001, *The Financial Performance*). As DeYoung observes, the introduction of online banking has parallels to the introduction of automated teller machines (ATMs), which provided a convenient way to engage in traditional banking transactions. Perhaps the most important feature of traditional banking that is missing with online banking is that a customer cannot get cash online. An important point that DeYoung makes is that Internet-only banks have a harder time obtaining higher-yield assets such as loans. The lack of a branch network for online banks therefore hurts relationship lending.

Cash had long been an important component of the payment services provided by banks. Indeed, for the average person in the nineteenth and early twentieth centuries, traditional banking meant using banknotes as a means of payment; personal loans from banks were rare. Today, traditional banking means the use of a checking or NOW account (demand deposit) or savings account (time deposit). Individuals also expect a role for the government (state or federal) in ensuring the safety and soundness of banks.

Online banking uses new technology in the delivery of banking services, but it does not entail a basic change in the nature of those services. This is because much of banking is information-related and can therefore be delivered electronically (Nickerson and Sullivan 2003). Referring to Table 1, it is apparent that so far banks have not tried to do something different; customers have no new service to them that is not provided by a traditional bank. Banks have had to provide technical support to consumers and have had to be prepared to make corrections when customer errors occur. The best banks adapt quickly to these new services. Banks also help with the accounting and monitoring of accounts through making the customer's bank information available for download into software such as Quicken or Money. This service enables the customer to monitor and track transactions, and also helps in the preparation of income taxes. The development and widespread use of software such as Quicken and Money has meant that banks often provide the ability to download account information into a format that can readily be imported into the customer's financial planning software (Furst and Nolle 2004).

Online banking is only part of the electronic revolution in banking. Examples of electronic banking include direct deposit of pay directly into a bank account, ATM cards, debit cards, and preauthorized debits, which allow customers to have regular, recurring bills paid automatically (Anguelov, Hilgert, and Hogarth 2004). There are also products that are not connected to a bank account, such as stored-value cards and smart cards; these have a preloaded value that need not be deducted directly from a bank account. Though these are important parts of the change in the payments system, the focus of this chapter will be those activities specifically connected to a bank account through the use of the Internet.

WHO USES ONLINE BANKING?

The diffusion of new technologies in society is an important topic (Bradley and Stewart 2003). There are both

supply and demand considerations that affect the rate at which a new technology is adopted in society (Dinlersoz and Hernandez-Murillo 2005). In the case of banking, as more individuals and firms adopt the technology, there is a greater incentive for others to adopt it as well.

An important impact of online banking has been on the costs of doing banking for the banks and their customers (both individuals and businesses) (Bauer and Hein 2005). Online banking has reduced many of the costs of providing payments and lending services (trips to the bank), but it may have raised other costs such as account monitoring by individuals (Kim, Widdows, and Yilmazer 2005). The most immediate way that online banking differs from traditional banking is that transactions occur without the need to interact face to face with a bank employee. For banks, this typically means fewer interactions with bank tellers or loan officers. The use of tellers to conduct business is costly, as banks have known for some time. One estimate is that branch banking costs \$1.07 per transaction, telephone transactions 55 cents each, ATMs 27 cents, and online banking about 1 cent per transaction (DeYoung 2001, *The Internet's Place*). These estimates give an idea of the magnitude of the potential cost savings for banks with greater use of online banking.

One reason banks are considered "special" is the customer relationship that is fostered through the use of the teller and personal loan officers. On the one hand, the adoption of online banking is an effort by banks to reduce their costs, but on the other hand, it may put in jeopardy that special customer relationship. Thus, benefits for the bank on the cost side may also impact the revenue side if customers no longer perceive banks as "special" providers of payments and lending services. Online banking creates new pieces to the customer relationship. When a customer gets accustomed to using a bank's online system, much of the customer's routine payment information may get entered into a bank's online system. It becomes easier to switch into other products the bank offers, and the bank's Web site provides it with new, low-cost opportunities to supply information to customers about banking products they might want. These features of online banking could make a relationship more important and would add a whole new set of complications that a customer would have to go to the trouble of changing if he or she moved to another bank.

Banks will offer online banking if they believe it will ultimately improve their profits. Given competition, they may be forced to adopt the technology though it may not be profitable in the short-run. Lang, Nolle, and Furst (2002) found that though the more profitable banks were the ones more likely to adopt Internet banking after Quarter 2 1998, they were less likely to be the first institutions to adopt Internet banking. They also found that among banks with assets over \$100 million, institutions with transactional Internet banking were generally more profitable and tended to rely less heavily on traditional banking activities. Further, for banks with less than \$100 million in assets, there was no statistical difference in profitability among mature Internet and non-Internet banks. One important finding for online banking was that the startup Internet banks were significantly less profitable than startup non-Internet banks (Lang, Nolle, and Furst 2002).

Figure 1: The Diffusion of Internet Banking 1999–2005 (Sullivan and Wang 2005)

Figure 1 plots the diffusion trends of Internet banking. It shows that 35 percent of depository institutions reported a Web site address in 1999, rising to 79 percent in 2005. Moreover, 53 percent of depository institutions reported Web sites with transaction capabilities in 2003, rising to 70 percent in 2005. Though data on transactional Web sites are not available for the whole sample of commercial banks before 2003, an independent survey conducted by the Office of the Comptroller of the Currency (OCC) shows that 6 percent of national banks adopted transactional Web sites in 1998, and the proportion rose to 37 percent in 2000 (Sullivan and Wang 2005; Chang 2005).

An interesting comparison for the diffusion of online banking is to consider the number of years it took for various types of technology to reach 30 percent penetration of the U.S. market. For the telephone, it was 38 years, television 17 years, personal computers 13 years, and the Internet 7 years. Sullivan (2004), in a survey of Tenth Federal Reserve District banks, found that fewer than 3 percent of the banks had transactional Web sites in 1999, but by 2004, nearly 46 percent had such sites that allowed customers to access and execute transactions on their accounts. Though banks have offered transactional services, estimates for the entire United States show that households using online payments grew from 2.6 percent in 1998 to 25 percent in 2003 (Sullivan 2004).

Individuals respond to relative prices, but they also have preferences that are determined by habits and other factors that influence their decisions on whether to adopt new technologies (Anguelov et al. 2004). Today, about 40 million U.S. households actively use online banking accounts (Wang 2006). Those who were already computer- and Internet-savvy were quick to adopt online banking. These are individuals with some sophistication in computer usage, who trust the security of online transactions, and who can conduct business without necessarily needing to visit brick-and-mortar banking offices. The distribution of this group varies with education, income, and other factors, including access to a personal computer (Sarel and Marmorstein 2004).

The demographic characteristics of those who were early users of computer banking can be seen in Table 2. The category of computer banking users is somewhat broader than online banking users, since the former could include those who may be using modem access to dial directly into the financial institution's computer and using proprietary software to access those financial services. However, the demographic characteristics of computer versus online banking users would likely be very similar.

In general, users of computer banking had higher incomes, were younger, and were more educated than non-users. In addition, more users were white, married, held a job, and owned their own home. As costs fall and computers are more widely available, a greater portion of the population is able to use computer banking. The differences between users and nonusers provide some guidance on where banks should focus for new customers and also as a guide for public policy to increase access to financial services for a wider range of constituents.

There is also some evidence that rather than online banking being a substitute for traditional ways of delivering banking services, it is in fact a complement (DeYoung 2001, *The Internet's Place*). Though there has been a decline in check usage as the use of online banking has grown, banks have also increased the number of offices. In addition to the now-familiar ATMs, banks have also used automated banking machines (ABMs), which combine ATM and online services through the use of "kiosks" (DeYoung 2001, *The Internet's Place*).

WHAT ARE THE RISK AND SECURITY ISSUES IN ONLINE BANKING?

Today, most online bank users are able to access their bank accounts through the use of a Web browser such as Internet Explorer, Mozilla, Firefox, Safari, and others. As Sullivan (2004) notes, there are changes in both the technical and procedural ways in which online banks do business that expose them to operational risks. By providing access over the Internet, there is the risk that information

Table 2: Demographic Characteristics of Users and Nonusers of Computers Banking

	1995		2001	
	Users	Nonusers	Users	Nonusers
Household median income (2001 dollars)	53,168	38,950	71,953	38,032
Household financial assets, median (2001 dollars)	35,714	18,504	81,350	21,500
Age of head of household, median (years)	40	46	42	49
Education of head of household, median (years)	15	13	16	12
Race/ethnicity of head of household, distribution (percent)				
White	81	83	87	78
Black	15	9	7	13
Hispanic	3	5	2	7
Other	2	4	5	2
Marital status of head of household, distribution (percent)				
Married	65	61	74	60
Single female	20	26	13	27

Source: Anguelov et al. (2004).

may be acquired by an unauthorized person. The online user must be authenticated by the security system. Banks must work to ensure that they allow only authorized access to the system and can protect against account fraud and identity theft.

There is concern that customers could give out their account information inadvertently. Through various means, customers may be persuaded to provide account and password information or be directed to fake Internet sites. *Phishing* is a scam that involves the obtaining and using of an individual's personal or financial information, usually through an e-mail sent from what appears to be a financial institution, government agency, or other entity that requests personal information. The e-mail often contains a link that directs the recipient to a phony Web site. Once the individual goes to this Web site, personal information such as Social Security number, account numbers, passwords, and so on, may be requested. If the consumer provides this information, it can be used fraudulently to access consumer accounts or assume the person's identity.

Pharming refers to the redirection to an illegitimate Web site through technical means that may redirect a consumer when trying to access his or her bank's Web site (FDIC [Federal Deposit Insurance Corporation] 2005). Pharming can occur through static domain name "spooking." An example of spooking is when a pharmer may direct a user to anybnk.com instead of anybank.com, the site the consumer intended to access. Also, malicious software in the form of viruses or "Trojans" can intercept a user's request to visit a particular site and redirect the user to a site that the pharmer has set up. A hacker may also steal or hijack a company's legitimate Web site, allowing the hacker to redirect all legitimate Internet traffic to the fraudulent site. This is referred to as "domain hijacking," and can be done by slamming (submitting a domain transfer request from one registrar to another) or through the failure of a legitimate company to maintain the lease on the Web site. The most dangerous form of pharming is when the domain name server (DNS) translates the phrase entered into the Web browser into an Internet protocol address (IPA) and the user's connection

is routed to a site other than that requested. This DNS poisoning can occur as a result of misconfiguration, network vulnerabilities, or malicious software (referred to as malware) installed on the server. For the entire Internet, there are thirteen root DNS servers that are closely protected and controlled. If a hacker were to penetrate one or more of these root servers, the Internet could be severely compromised (FDIC 2005). Banks and their customers can take steps to prevent such phishing and pharming attacks. These include digital certificates used by legitimate Web sites to differentiate themselves from illegitimate sites. Financial institutions need to be vigilant in renewing their domain names and must investigate the possibility of registering similar names to avoid unauthorized domain slamming and investigate any anomalies about their Web site to ensure that DNS poisoning attacks are addressed promptly. Consumer education is also essential to maintaining a safe system (FDIC 2005).

One example of large-scale Internet fraud is what happened to the Swedish bank Nordea. It lost up to \$1.1 million in what security company McAfee is describing as the "biggest ever" online bank heist. The attack was a tailor-made Trojan sent in the name of the bank that encouraged clients to download a "spam-fighting" application. Users who downloaded the attached file, called *raking.zip* or *raking.exe*, were infected by the Trojan. Once installed, the program recorded keystrokes, and users were redirected to a false home page, where they entered important log-in information, including log-in numbers; then an error message appeared saying that the site was experiencing technical problems. The data were then harvested by the criminals, who used it at the real Nordea Web site to remove money from customer accounts. Bank spokespersons reported that the problem was not a lack of security at the Nordea site, but rather customers opening the Trojan virus and not having updated antivirus software installed on their computers. The bank refunded losses to its customers (Espiner 2007).

Once financial institutions have taken all precautions to maintain the integrity of their DNS, then the most important security measures concern log-ins to the site by their customers. This is done through various methods of authenticating the user. This process must be secure. Transport layer security (TLS) is a cryptographic protocol that provides secure communications on the Internet for financial transactions and other data transfers. It replaces an earlier protocol, secure socket layers (SSL). The TLS protocol allows client/server applications to communicate to prevent eavesdropping, tampering, and message forgery. 3-D Secure™ is an XML-based protocol to allow authentication of cardholders of credit-card companies in electronic payment transactions. The protocol ties the financial authorization process with an online authentication. In order for a member bank to use the service, it must operate a compliant software that supports the latest protocol specifications.

The authentication factor is typically something that customers provide as a means of identification. These factors are either something a person knows (such as a personal identification number, or PIN), something a person has (such as a physical device that has to be attached to the computer—e.g., a USB token device), or something a

person is (such as a fingerprint, voice pattern, or pattern of veins in the user's eye). The latter type of identification is referred to as "biometrics" (FFIEC [Federal Financial Institutions Examination Council] 2005).

The authentication methods vary from a simple one-factor method requiring a password, to double-factor methods requiring a password and additional information input or a physical device or card. To meet the standards set by the bank regulatory agencies, banks have increasingly moved to multifactor authentication. On the initial log-in page, the customer may be asked to input a log-in name and also a series of numbers that appear at random below the log-in name. After clicking to go to the next page of the log-on process, the customer is presented with a customer preselected image and a place to input the account password. Such log-in procedures increase the level of security, but also require more time and effort from the customer. Missouri-based Midwest Independent Bank's system presents customers with nine faces in a tic-tac-toe-like grid and requires them to identify the right one and click on it. All of the bank's customers are required to choose a stranger's face and remember that face. Another large institution, Wachovia Bank, requires customers to enter separate access codes in addition to log-in names and passwords. SunTrust Banks Inc.'s new security will be written into software used behind the scenes that most customers will not notice (Matthews 2007). Because individuals do not always have all of their financial assets in a single firm; they may be faced with a bewildering collection of log-in names, passwords, images, and other such log-in authentication factors. The banks must find a balance between enhanced security, which their customers and the regulatory agencies both require, while maintaining the high level of convenience and ease afforded by online banking.

Of course, the security of a particular method depends on the integrity of its implementation. In addition to using passwords and PINs, other types of information-based authentication include online questions or queries that require a specific answer. These security methods can be enhanced if there is also the requirement that they be periodically changed. This may be an unwanted inconvenience for the customer, but Web browsers can retain passwords and information can be stored on the personal computer or elsewhere for quick reference, though this may raise concerns about security on the individual's computer.

The use of physical devices such as a USB token that plugs directly into a computer's USB port does not require any special hardware on the user's computer. Such a device provides additional security, especially if used in combination with something that a person knows, such as a password. Again, as the level of security increases, it may require greater responsibility from the individual not to lose such a device or token. The USB tokens are one-piece, injection-molded devices that can store digital certificates that can be used in a public key infrastructure (PKI) environment (FFIEC 2005). To date, a small number of large banks are using this technology.

Two other physical devices that can be used are smart cards and password-generating tokens. Though not currently in widespread use, they represent alternative

technologies. Smart cards can be inserted into a compatible reader that is attached to a customer's computer. Such cards are hard to duplicate, are tamper-resistant, and are easily portable. A password-generating token ensures that the same one-time password (OTP) is not used consecutively. The OTP is displayed on a small screen on the token after the customer enters a user name and password. Authentication requires that the regular password and the new OTP match those on the authentication server. Because of the element of randomness, such devices increase the difficulty for a cyber thief attempting to break into a system (FFIEC 2005).

One of the most recent methods for authentication, biometric technology, is based on identifying physiological characteristic such as fingerprints, iris configuration, or facial structure. At present, these technologies are being tested by a few institutions involving very large financial transactions (hundreds of millions of dollars). The process of introducing people into a biometrics-based system is referred to as "enrollment." During enrollment, a sample of data is taken from one or more physiological or physical characteristics and the samples are converted into a mathematical model or template. Once the information is stored in a database, a software application can be used to perform the analysis. The customer then interacts through a live scan that is compared with the registered template stored in the system. Provided there is a match, the person is authenticated. In addition to the identifiers already mentioned, other possibilities are voice recognition, keystroke recognition, handwriting recognition, and finger and hand geometry (FFIEC 2005).

Two biometric techniques available are fingerprint and face scans. Fingerprints have long been used, prior to the computer age, and fingerprint biometrics is generally considered easier to install and use than iris scanning. The FFIEC recommends fingerprint technology for large-dollar transaction accounts. Face recognition, a newer technology, focuses on specific features of the face and makes a two-dimensional map of the face. Obtaining good scans requires proper lighting and placement of the video device for collecting the image. Several cameras may collect image data, and tests for authenticity can also be included to eliminate the chance that the person is using a photograph of an authorized person.

Though the above methods require an increasing level of sophistication on both the hardware and software sides, lower-level technologies are also available. These include the use of scratch cards as a low-tech version of the OTP tokens. Another method is to use the telephone or fax or regular mail to confirm a transaction. The customer's response to this confirmation request may require an additional password or other identifying information. Another low-cost way to verify a customer is to know the identity of the person at a specific IPA. There may, however, be problems with verifying IPAs, because they may be changed frequently or they could be fake. There are software fixes for such problems, but again there are problems associated with using proprietary software written for a particular platform. Geo-location software inspects and analyzes the small bits of time required for Internet communications to move through a network. Distances can be calculated and compared with those known for the user, and if they seem

unreasonable, the user will not be authenticated. One other level of authentication is that banks could provide authentication to their customers before sending sensitive information. This would help deal with the problems encountered when customers are directed (through e-mails or otherwise) to false Web sites that look like the actual sites but are intended only to collect the user's information (FFIEC 2005).

One other method that banks can use is to have the customer verify information that the bank has on record or can obtain from a third party. In making online loans, banks will want to ensure that they have the right person, so they can match up credit information or geographical location with information from a third party such as a credit rating agency. Banks can also verify that address, area code, and ZIP code information are consistent. Banks can also use information regarding known fraudulent behavior to screen customers (FFIEC 2005).

As a result of the guidance issued by the FFIEC, many U.S. financial institutions redid their authentication protocol in 2006. Banks are supposed to tailor authentication efforts to risks of transactions (FFIEC 2005). It appears that the method of choice that financial institutions have adopted is a challenge-and-response system. Customers are first asked to provide answers to a random set of questions, which are stored on the financial institution's computer system. If the financial institution's Internet banking system detects a security risk, it can challenge the user and ask for the answers to one of these questions. One security risk, for example, is when a funds transfer is requested. Also, computer profiling has become common; the Internet banking system can detect characteristics of the user's computer. An Internet banking session is considered lower risk if it is initiated from a computer with a profile with which the system is familiar. If it is initiated from an unfamiliar computer, it would trigger the challenge-and-response mechanism.

Though customers access their accounts via the Web, the actual software used by banks is dominated by only a handful of vendors. Sullivan (2004) reports that in the Tenth Federal Reserve District (Kansas City headquarters), the top software vendor accounted for 20 percent of the online banking software used by banks in the district. Hence, if the software used by a large number of firms were compromised, the impact could be dramatic, and could intensify any fraudulent transactions problems. Because of the potential for large losses, there is a strong incentive for both the software vendors and the banks to be vigilant in security measures.

The Regulation of Financial Institutions

Though banks have a self-interest motive to protect their customers, there are also government regulations and laws with which banks must comply. Most recently there are the various regulations of the Gramm-Leach Bliley Act, the USA Patriot Act (section 326), and the Sarbanes-Oxley Act. These laws require that banks and savings associations safeguard the information of all persons who obtain financial services through a federally insured institution. Similar legislation covers credit unions and many other

types of financial institutions as well (Mann 2006; Sullivan 2006).

The bank regulatory agencies have been aggressive in promoting online banking security. The Federal Financial Institutions Examination Council (www.ffiec.gov) provides a centralized source of information on the safety and security directives and information from the federal regulatory agencies such as the OCC, the FDIC, and the Federal Reserve. These responsibilities come from the basic mandate for bank regulatory agencies to maintain the safety and soundness of the financial system (Spong 2000). The government agencies are either part of the Central Bank or the Treasury Department (or Ministry of Finance). In the United States, the Federal Reserve System both provides liquidity to financial institutions in times of localized or systemic crisis and regulates and supervises financial institutions. The FDIC is the agency responsible for resolving any solvency questions and oversees the bank insurance fund, while the OCC charters and regulates national banks. One important reason government began to regulate banking was to protect the depositor against losses incurred by the bank in the event of a liquidity or solvency crisis. The creation of the FDIC in 1933 was a direct result of the problems of bank runs and bank failures (Rogers 2005).

Bank runs occur when depositors withdraw their money from their accounts. In the United States, regular accounts are insured up to \$100,000. Economists make a distinction between “lobby run” and “clearinghouse” run. Lobby runs, initiated by small depositors, are no longer important because of deposit insurance. Clearinghouse runs (which apparently occurred when Continental Illinois failed in the 1980s) are still important, because large depositors are uninsured. With the advent of the Internet, clearinghouse runs could occur more quickly as large depositors execute withdrawals through their online connections.

The widespread use of online banking, with its implied increased monitoring by bank customers, could help reduce the need for monitoring by bank regulatory authorities. Such a development would reduce the regulatory burden on banks and help promote a safe banking system. Though online banking could reduce monitoring costs, Berentsen (1996) believes that today banks are more vulnerable to bank runs because news and rumors spread quickly over public computer networks. The problem is one of contagion; one bank may have problems, and the public may assume that this means other banks also have problems. When information is accurate, the potential for a bank run is a disciplining factor on banks, but if the information is incorrect, it may have a strong negative impact on the stability of the banking system.

CONCLUSION: WHAT IS THE FUTURE OF ONLINE BANKING?

Over the past decade and a half, legislation and technological advances have resulted in fewer numbers of bank charters. The demise of geographical restrictions on bank offices and branches due to legislation passed in 1994 has meant a consolidation of the banking industry into

a smaller numbers of firms. At the same time, economic growth has increased the demand for financial services. Though online banking will likely continue to grow for the foreseeable future, this does not mean that traditional banking will disappear anytime soon. Evidence of this is that over the past decade, as the Internet and online banking have expanded, so has the growth in the number of bank branches. As previously noted, this indicates that online banking is a complement to the more traditional methods of delivering financial services.

The use of the Internet for payments may call into question the special role of banks. Banks have traditionally been at the front end of payments (interacting with the consumer), which has been aided by their monopoly access to the payments system. But now many nonbanks, such as PayPal, are taking the front-end role. They provide payment initiation and banks are relegated to the (less visible) back-end processing of payments. Nonbanks, in fact, are important sources of payment innovation. But this may also mean that the bank monopoly on access to payments is less important in terms of customer relationships. There is a concern, however, that nonbank access to payments could bring new risks to payments. Restricting access to banks has arguably kept payments relatively safe because risk control is easier with a closed, homogeneous system. Allowing nonbank access to the payments system may be desirable public policy but it would need to be done carefully (Quinn and Roberds 2003).

The challenges facing online banking for banks, customers, and government regulators are different but intertwined. Though there appear to be great cost savings from the point of view of banks when it comes to using online services, from the point of view of someone who wishes to make a payment transaction, the use of cash is most often the quickest and lowest-cost. The reason for this is that cash is readily available, it is convenient to carry, and most daily transactions are in small amounts. One factor important in the spread of online banking is to find a means of payment that will induce payers to use an electronic means of payment instead of cash (McGrath 2005). At present cash remains a useful means of payment for many transactions—and not all of those are necessarily illegal. If it becomes possible to transfer value from a checking account to a cash card, then this could change the future evolution of the payments system dramatically.

GLOSSARY

ACH: The Automated Clearing House, which processes payments electronically, was designed to reduce the use of paper checks for routine payments.

Authentication: The process of verifying the identity of a person or entity using online banking services.

Computer Banking: Banking services that consumers can access, by using an Internet connection to a bank's computer center, in order to perform banking tasks, receive and pay bills, and so forth.

Direct Deposit: A form of payment by which an organization (such as an employer or a government agency) pays funds (such as pay or benefits) via an electronic transfer. The funds are transferred directly into a consumer's bank account.

Direct Payment (also Electronic Bill Payment): A form of payment that allows a consumer to pay bills through electronic fund transfers. Funds are electronically transferred from the consumer's account to the creditor's account. A direct payment differs from a preauthorized debit in that the consumer must initiate each direct payment transaction.

Electronic Check Conversion: The process by which information from a check (routing number, account number, and amount of the transaction) is converted into an electronic format in order to make a one-time electronic fund transfer from an account.

Multifactor Authentication: A method to combat bank fraud that requires something the user possesses (i.e., the card) combined with something the user knows (i.e., PIN) before access to financial account information is allowed.

Smart Card: A type of stored-value card in which one or more chips or microprocessors are embedded, making the card capable of storing data, performing calculations, or performing special-purpose processing (to validate personal identification numbers, authorize purchases, verify account balances, and store personal records).

Stored-Value Card: A card on which monetary value is stored, through either prepayment by a consumer or deposit by an employer or other entity. For a single-purpose stored-value card, the card issuer and acceptor are generally the same entity, and the funds on the card represent prepayment for specific goods and services (for example, a phone card). A limited-purpose card is generally restricted to well-identified points of sale within a given location (e.g., vending machines at a university).

INTRODUCTION

Defining Digital Libraries

Digital libraries take advantage of the networking facilities of the Internet to offer quality content from authoritative sources, such as libraries and universities; they can be characterized as the “high end” of the Internet: that sector of the Internet that maintains a tradition of shared resources and easy access.

A major textbook for the field offers the following definition of a digital library:

First, the digital library must have content. It can either be new material prepared digitally or old material converted to digital form. It can be bought, donated, or converted locally from previously purchased items. Content then needs to be stored and retrieved. Information is widely found in the form of text stored as characters, and images stored as scans. These images are frequently scans of printed pages, as well as illustrations or photographs. More recently, audio, video, and interactive material is accumulating rapidly in digital form, both newly generated and converted from older material. Once stored, the content must be made accessible. Retrieval systems are needed to let users find things; this is relatively straightforward for text and still a subject of research for pictures, sounds, and video. Content must then be delivered to the user; a digital library must contain interface software that lets people see and hear its contents. A digital library must also have a “preservation department” of sorts; there must be some process to ensure that what is available today will still be available tomorrow. (Lesk 2005, 2)

A digital library must contain and manage content; a system that simply points to outside information resources

cannot be considered a true digital library. The literature uses three parallel terms: *digital*, *electronic*, and *virtual libraries*; these terms are normally used interchangeably (Saffady 1995). In current usage, *digital library* is preferred in North America whereas Europeans tend to use *electronic library*; the blanket term, *digital collections*, is little used. Definitions of digital libraries have been intensively discussed, notably in a survey by Schwartz (2000), in which she discovered sixty-four formal and informal definitions of *digital library*, and in a chapter by Borgman (2000, 40–4), which examined various approaches to the terminology. An entire chapter of Chowdhury and Chowdhury's (2003) textbook *Introduction to Digital Libraries* was dedicated to definitions and characteristics of the field.

Institutional and Informational Resources in the Digital Library Field

The Digital Library Federation, based in Washington D.C., is a consortium of thirty-nine major libraries, plus related institutions (www.diglib.org). It maintains a Digital Collections Registry at <http://dlf.grainger.uiuc.edu/DLFCollectionsRegistry/browse>. This offers simple or advanced searching of the descriptions of more than 750 digital libraries.

Resource pages for the digital library field are maintained by Ben Gross at the University of Illinois (<http://bengross.com/dl>), Candy Schwartz at Simmons (<http://web.simmons.edu/~schwartz/dl.html>), and at the University of California at Berkeley's SunSITE (<http://sunsite.berkeley.edu>). Major textbooks for the field have been authored by Lesk (2005), Chowdhury and Chowdhury (2003), and Arms (2000). A book by Tedd and Large (2005) discusses digital libraries in a global environment. Overviews of the field have been produced by Fox and Urs (2002) and McCarthy (2004). Chowdhury and Chowdhury (2000) compared the information-retrieval features of twenty important digital libraries. Greenstein and Thorin

(2002) prepared a biography of the digital library, based on six case studies.

Special government grants are a major source of financing in the digital library field. The National Science Foundation's Digital Libraries Initiative was of great importance to digital library development in the United States. Projects financed in Phase 1, 1994–1998, can be seen at www.dli2.nsf.gov/dlione; they were discussed by Fox (1999). Phase 2 projects are available at www.dli2.nsf.gov; they were summarized by Lesk (1999). One of the most important sources at the moment for the financing of digitization projects in the United States is the Institute of Museum and Library Services (IMLS; www.imls.gov). For examples of projects that have received IMLS support, go to www.imls.gov/search.asp and search for grants in areas such as "Preservation or digitization."

The Inventory of Canadian Digital Initiatives lists and describes Canadian information resources created for the Web (www.collectionscanada.ca/initiatives/index-e.html). The EnrichUK program (www.enrichuk.net), supported by British lottery funds, provides free access to 150 sites displaying the country's cultural, artistic and community resources. For a description, see Nicholson and MacGregor (2003). McCarthy and Cunha (2003) discuss digital library development in Brazil.

Digital library research was first reviewed by Chowdhury and Chowdhury (1999). This was updated by the chapter on "Digital Library Research" in Chowdhury and Chowdhury's *Introduction to Digital Libraries* (2003, 35–66). It is natural that the digital library area is well served by e-journals. In the United States, the major e-journal is *D-Lib Magazine* (www.dlib.org; Figure 1).

Other journals are *Ariadne* (www.ariadne.ac.uk), from Britain, and the *Journal of Digital Information* (JoDI; <http://journals.tdl.org/jodi>), from Texas. The major U.S. conference for this area is the Joint Conference on Digital

Libraries (JCDL; www.jcdl.org); it is sponsored by Association for Computing Machinery (ACM) and the Institute of Electrical and Electronics Engineers (IEEE). European professionals participate in the European Conference on Research and Advanced Technology for Digital Libraries (ECDL), while Asian professionals go to the International Conference on Asian Digital Libraries (ICADL).

Digital libraries already demonstrate remarkable diversity, despite their short history. The next section presents an abbreviated overview of categories of digital libraries; for more detailed discussions, see my article in *The Internet Encyclopedia* (McCarthy 2004), or "A World Tour of Digital Libraries," in Lesk's *Understanding Digital Libraries* (2005, 321–60).

CATEGORIES OF DIGITAL LIBRARIES

Image-Oriented Digital Libraries

An important proportion of digital library materials consists of photographs and still images. These are relatively easy to digitize; they may avoid some of the copyright problems related to printed texts and can easily become the basis of attractive Internet presentations. For a major example see the 160,000 black-and-white Farm Security Administration photographs at the Library of Congress, which offer a picture of American rural life during the Depression (<http://memory.loc.gov/ammem/fsowhome.html>; Figure 2); keyword, subject, creator, and geographic indexes are available.

Another major collection is at the Bancroft Library, the University of California, Berkeley, which makes available the 37,000 image California Heritage Collection (<http://sunsite.berkeley.edu/CalHeritage>). Smaller collections have been digitized in numerous cities and states worldwide; historical photographs support local

D-Lib[®] Magazine

The screenshot displays the D-Lib Magazine website interface. At the top, there is a search bar with the text "Search" and a "Go" button. Below the search bar, the page is organized into several columns. The left column contains a sidebar with links for "About D-Lib Magazine", "Current Issue" (including Table of Contents, Featured Collection, In Brief, and Clips & Pointers), "Indexes" (Back Issues, Author Index, Title Index), "Subscriptions", "Search Guidelines", "Mirror Sites", "Author Guidelines", "Contact D-Lib", "DOI" (10.1045/dlib.magazine), "ISSN" (1082-9873), and an "RSS" feed link. The middle column, titled "In the Current Issue", lists the "November 2005 Vol. 11 No. 11 Table of Contents" and highlights several articles: "EDITORIAL Designing for Success" by Bonita Wilson, CNRI; "LETTERS To the Editor"; "OPINION Public Domain Art in an Age of Easier Mechanical Reproducibility" by Kenneth Hamma, J. Paul Getty Trust (doi:10.1045/november2005-hamma); and "COMMENTARY What is a Digital Library Anymore, Anyway? Beyond Search and Access in the NSDL" by Carl Lagoze, Dean B. Krafft, and Sandy Payette, Cornell University, and Susan Jesuroga, UCAR-NSDL (doi:10.1045/november2005-lagoze). The right column, titled "Also This Month", features a "Digital Collections" section with a "FEATURED COLLECTION" titled "Historic Pittsburgh Image Collections", which includes a small image and text about the collection. Below this, there are sections for "In Brief", "In the News", "Clips & Pointers", "Archives", and "Back Issues and Indexes".

Cette collection numérisée a été produite aux termes d'un contrat pour le compte du Programme des Collections numérisées de Rescol, Industrie Canada

community feelings. For a typical example, see the photographs from the Montréal city archives in *Montréal: Municipalité-Métropole 1920-1960* (<http://epe.lac-bac.gc.ca/100/205/301/ic/cdc/mtl/default.htm>; Figure 3).

Other types of images can also be made available in digital library collections. Visually stunning Spanish Civil War posters have been digitized at the University of California at San Diego (<http://orpheus.ucsd.edu/speccoll/visfront>; Figure 4).

Book-Oriented Digital Libraries

Project Gutenberg, often considered the first significant digital library, has always concentrated on simple

presentations of books (www.gutenberg.net). It was founded in 1971 at the University of Illinois, and originally offered FTP downloads of “plain vanilla” ASCII texts, readable on almost any platform. Many of Project Gutenberg’s 20,000 free texts are now available in HTML; input is processed by volunteers. The University of Michigan is responsible for several significant book-oriented projects, notably *Making of America* (<http://quod.lib.umich.edu/m/moagrp>; Figure 5). This contains approximately 10,000 books and 50,000 journal articles on nineteenth-century American social history from the Antebellum period through Reconstruction. Sophisticated software offers a choice of image, text, and PDF files, in normal, large, and small size.

Figure 4: Spanish Civil War poster, digitized at the University of California, San Diego

Figure 5: Screen from the Making of America Collection, the University of Michigan. Note bibliographic data, "Format" settings (image, text, PDF), "page size" buttons and controls to move from page to page

The University of Virginia Electronic Text Center (<http://etext.lib.virginia.edu>), founded in 1992, offers major resources in the humanities, including 10,000 publicly available online texts, and over 160,000 images. This attracts more than a million visitors each month; the Etext Center is also a valuable source of information on digitization procedures. It is important to note that digital libraries today exclude most modern commercially published books and the majority of copyright-protected items. These are exactly the texts that would be in high demand. The Digital Book Index (www.digitalbookindex.com) claims to list more than 130,000 English-language book texts, of which more than 90,000 are said to be free, but many texts are available in multiple versions. The Online Books Page (<http://digital.library.upenn.edu/books>), a wide-ranging catalog of online books, covers more than 25,000 titles.

Many early book-oriented digital libraries were established by universities and libraries for cultural motives. Commercially oriented digital libraries soon began to appear. One of the most successful in the North American market is NetLibrary, which has always concentrated on selling through libraries; it now offers more than 100,000 titles (www.netlibrary.com; Figure 6). It is so library-oriented that it permits access to only a limited number of copies of a book at any one time. This might appear unusual, because the Internet permits simultaneous access to an unlimited number of digital copies, but this limitation encourages publishers to join the scheme. The software does not permit rapid printing of multiple pages. NetLibrary is a subsidiary of OCLC (Online Computer Library Center; www.oclc.org), a cooperative system that supplies cataloging data and related digital services to more than 57,000 libraries in 112 countries and territories around the world.

Questia (www.questia.com) digitized core collections in the social sciences and humanities, and now offers over 67,000 books and 1.5 million articles through a sophisticated software interface. Questia is based in Houston, and sells subscriptions to the general public. Paid access services in the area of computing are dominated by the Association for Computing Machinery (ACM) Digital Library (<http://portal.acm.org/portal.cfm>). The ACM has been extremely successful in leveraging its informational resources to an audience with a high level of computer literacy. Another source for texts in the same area is Safari Tech Books Online (<http://safari.oreilly.com>), which offers digital versions of texts on computer science and programming from O'Reilly and other companies.

The systems cited above use Internet browsers as a distribution system, but some important commercial alternatives deserve mention. In the year 2000, half a million people downloaded Stephen King's e-book, *Riding the Bullet*; this can be considered the beginning of the commercially produced e-book. Numerous formats are offered, including Adobe Acrobat PDF (portable document format), Microsoft's downloadable e-book software, MS Reader, and the Palm and Mobipocket formats for mobile devices and PDAs. A major company in the field is Rosetta Books (www.rosettabooks.com; Figure 7), which offers e-books in all four formats. This publisher won a legal victory in 2001 when Random House objected to them distributing electronic versions of texts by William Styron, Kurt Vonnegut, and others. The judge considered that e-books constitute a separate medium from the original printed products, because they offer additional electronic advantages, such as full-text searching and hyperlinking (Stein 2001). Contracts in which authors had assigned rights to publish "books" would, therefore, not automatically cover the electronic texts.

Figure 6: A sample screen from NetLibrary

There has been major growth in digital library systems offered by search engines or major e-commerce sites. Consumers in traditional bookstores have always had the right to flip through a few pages of the text. Amazon.com (www.amazon.com) began to permit this in a digital archive, initially of 120,000 books (Wolf 2003). Users can search the entire text, but printing is impossible and only

Meanwhile, the publicity given to Google's plans attracted the attention of other major players in the highly competitive search-engine world. Late in 2005 the Open Content Alliance brought together Yahoo!, Microsoft, the

Internet Archive, Hewlett-Packard, Adobe, and major universities (Quint 2005). They plan major book digitization at the Open Library project (www.openlibrary.org); Microsoft Network (MSN), for instance, has pledged \$5 million to digitize approximately 150,000 books. Copyrighted texts will be included only with the agreement of the publisher; it will be possible to order hard copies through a Print-on-Demand service. Also late in 2005, a World Digital Library was announced by the Library of Congress; this would make available online rare and unique cultural materials held in U.S. and Western repositories, together with those of other great cultures beyond Europe, such as Asia, the Islamic world, and Africa (Library of Congress 2005). The first private-sector partner in this undertaking was Google.

Electronic Journals (E-Journals)

Digital penetration in the area of e-journals has been intense, and can often be both controversial and commercially driven. Three main areas of activity can be distinguished: commercial, semicommercial, and free e-journals.

During the second half of the twentieth century, the production of scientific and technical journals came to be dominated by a small number of commercially oriented companies. These became known for constantly increasing prices, but libraries maintained their subscriptions because researchers and professors considered the journals essential for their research. At the end of the past century, e-journals began to appear, but they offered libraries little relief. Major journal publishers began to offer both electronic and paper versions of their titles, but subscribers often found little advantage in subscribing to only the electronic editions. Titles are bundled, publishers discourage cancellation of individual titles, and libraries

are forced to take titles of little interest to them while the prices of the bundles increase steadily. Discussions of these problems (Knight 2003; Carnevale 2003) frequently mentioned journals published by Elsevier (www.elsevier.com). The Association of Research Libraries has mounted the "Create Change" campaign, in favor of the digital sharing of research results (www.arl.org/create/index.html). Elsevier electronic journals are available through Science Direct (www.sciencedirect.com), which offers controlled access to more than 2000 titles and 8 million articles. Elsevier is part of Reed Elsevier, a major Anglo-Dutch conglomerate (www.reed-elsevier.com). An important U.S. source for e-journal subscriptions is Ebsco, established decades ago to fulfill library journal subscriptions. It now permits libraries to access more than 12,000 e-journals and more than 6 million articles (<http://ejournals.ebsco.com/ejournals/ejsbro.pdf>).

Librarians and researchers see semicommercial approaches as the solution. The Public Library of Science (PLOS) is a nonprofit organization of scientists and physicians that treats the costs of publication as the final step of the research funding process (www.publiclibraryofscience.org). Its first title was *PLoS Biology*, launched in 2003; it is also responsible for *PLoS Medicine* and a series of other titles. All of its publications are subject to an open access license. Similar principles have been adopted by SPARC, the Scholarly Publishing and Academic Resources Coalition (www.arl.org/sparc/index.html), a collaborative system for academic e-journal production supported by the Association of Research Libraries. A Brazilian initiative, SciELO, Scientific Electronic Library Online, offers access to medical and scientific periodicals from Brazil, Chile, Spain, and other countries (www.scielo.org; Figure 8). It is based at the Regional Medical Library (BIREME) in São Paulo; more than 270 journals are available.

Figure 8: Opening screen of SciELO, Scientific Electronic Library Online, São Paulo, Brazil

[Access via Athens \(UK & Ireland\)](#)

Figure 9: Opening screen of JSTOR, the Scholarly Journal Archive, from the University of Michigan

Two major university initiatives offer members of participating academic institutions reasonably priced access to journals. More than 300 titles from sixty scholarly publishers are available from Project Muse, of Johns Hopkins University Press (<http://muse.jhu.edu>). Over 700 titles are available from JSTOR, the scholarly journal archive, organized by the University of Michigan (www.jstor.org; Figure 9).

There has also been a rapid expansion of free e-journals. The Internet Public Library (www.ipl.org/div/serials) describes numerous titles, arranged in carefully constructed subject categories. The World Wide Web Virtual Library offers an additional list of e-journals (www.e-journals.org). Preprint archive systems are also relevant in this context; arXiv (<http://arxiv.org>) permits rapid access to preprints in physics, science, and mathematics.

Digital Newspaper Collections

Nearly 70 million indexed newspaper pages are available online from NewspaperArchive for a monthly subscription (www.newspaperarchive.com). This Cedar Rapids company claims to add 2.5 million pages each month. Olive ActivePaper Archive software offers dynamic newspaper viewing capability (www.olivesoftware.com). This permits its users to click on any article, photograph, or

advertisement, which is then enlarged and presented in a separate window. For an example, see The Missouri Historical Newspapers Collection (<http://newspapers.umsystem.edu/archive/Skins/Missouri/navigator.asp>). Newspaper clippings are relatively easy to handle, and several collections are now available. For an indexed collection of clippings from newspapers published in the PacificNorthwest, see <http://content.wsulibs.wsu.edu/pncc/pncc.htm>. A collection of more than 144,000 Canadian newspaper articles, covering the Second World War, has been digitized and indexed at www.warmuseum.ca/cwm/newspapers/index.html.

Electronic Theses and Dissertations

The Networked Digital Library of Theses and Dissertations (NDLTD; www.ndltd.org) is the central organization for this field. For a practical example, see Virginia Tech, which offers nearly 10,000 digital theses (<http://scholar.lib.vt.edu/theses>). Experience suggests that digital availability stimulates use and promotes the author's reputation. West Virginia University reports more than 4 million hits on its digital theses (www.wvu.edu/~thesis/etd-faq.html); one notable thesis has already been downloaded more than 15,000 times. UMI Dissertation Publishing, of Ann Arbor, archives over 2 million doctoral dissertations and master's theses, and sells copies on demand. UMI, part

of ProQuest, now accepts electronic submission of theses (http://www.lib.umi.com/dissertations/about_etds).

Manuscripts and Ephemera

In a digital environment, there is no longer a clear line between libraries and archives. Papers of major personages in American history are available digitally from the Library of Congress. The papers of George Washington total 65,000 items (<http://memory.loc.gov/ammem/gwhtml/gwhome.html>); those of Abraham Lincoln total 20,000 (<http://memory.loc.gov/ammem/alhtml/malhome.html>). In 2003, 10,000 documents of Wilbur and Orville Wright were added to commemorate the centennial of their first flight (<http://memory.loc.gov/ammem/wrighthtml/wright-home.html>). The Internet is an appropriate medium for the transmission of ephemeral materials; therefore it is not surprising to find digital libraries that preserve and disseminate ephemera. One of Britain's oldest libraries, the Bodleian Library of Oxford University, offers a well-organized Broadside Ballads collection (www.bodleian.ox.ac.uk/ballads), which contains more than 30,000 items. Three thousand items of Historic American Sheet Music, including numerous items related to the Civil War from the collections of Duke University, can be found at <http://memory.loc.gov/ammem/award97/ncdhtml/hasmhome.html>.

Multimedia, Audio, and Video Digital Libraries

Digital libraries use computers for their interface, and therefore can present a variety of materials, such as books, photographs, film, and audio, with equal facility. The American Memory project of the Library of Congress (<http://memory.loc.gov>; Figure 10) is a major multimedia

collection and one of the world's most important digital libraries. It now includes more than 9 million items organized into more than 100 thematic collections; digital materials include rare books, manuscripts, photographs, maps, sound recordings, and moving pictures.

Another important multimedia collection is *ibiblio* (<http://ibiblio.org/index.html>), whose objective is to make information freely available for the public domain. It offers software, music, literature, art, history, science, politics, and cultural documentation and is supported by the Center for the Public Domain and the University of North Carolina at Chapel Hill. Apart from written texts, it also includes music and poetry archives, sports statistics, large text database projects, and software archives.

Fascinating materials from the dawn of the cinema can be found among the Early Motion Pictures of the American Memory collection (<http://memory.loc.gov/ammem/vshtml/vshtml.html>). The Prelinger Archives of Ephemeral Films, nearly 2000 short films, illustrating aspects of American life in the twentieth century, is available from the Internet Archive (www.archive.org/details/prelinger). History and Politics Out Loud is a major site dedicated to audio files (www.hpol.org), with speeches of Roosevelt, Churchill, and many others. The Open Video Project, from the School of Library and Information Science, University of North Carolina at Chapel Hill, offers more nearly 4000 video segments, retrievable by keyword or category (www.open-video.org).

CONSTRUCTING DIGITAL LIBRARIES

Digital libraries are complex structures that need to be carefully planned and designed. Their construction requires attention to a series of related considerations from the technical, legal, intellectual, and even aesthetic area.

Figure 10: Opening screen, American Memory, Library of Congress (<http://memory.loc.gov/ammem>)

Copyright and Digital Libraries

Copyright law was originally formulated to control the dissemination of printed materials. It adapts poorly to digital environments and creates a major constraint for digital library activities. Lesk's *Understanding Digital Libraries* includes an entire chapter on "Intellectual Property Rights (2005, 293–319). The U.S. Constitution grants copyright for "limited times," but copyright terms have been constantly extended, in recent years largely to protect the interest of film studios. The Sonny Bono Copyright Term Extension Act, 1998, fixed copyright in the United States at the life of the author plus 70 years. Pre-1978 works in copyright are protected for 95 years from the date copyright was first secured. Most materials published in 1923 or after are protected by copyright. For details, see the Public Domain and Copyright page of Project Gutenberg (<http://promo.net/pg/vol/pd.html>) or When Works Pass into the Public Domain (www.unc.edu/~uncclng/public-d.htm). Copyright protects everything fixed in tangible form: books, journals, newspapers, photographs, films, ephemera, and computer files, whether or not anybody is interested in protecting rights to these materials. About 10,000 books were published in the United States in 1930; today fewer than 200 are available from publishers (*Brief* 2002). The other 9800 could include texts that could usefully be digitized and disseminated, but the texts continue under copyright until 2019. They cannot be digitized, because copyright holders might appear. Contracts for most books published in the United States in the twentieth century stated that rights would return to the authors a few years after the book goes out of print (Lynch 2001). Should the authors die, their rights pass to their descendents, creating a huge category of "orphan books," for which no rights-holder can be traced. The situation is even more complex for photographs, sheet music, and ephemera. Eric Eldred, who founded the Eldritch Press (www.ibiblio.org/eldritch) to freely disseminate public domain texts, mounted a challenge to the copyright term extension laws, but lost in the Supreme Court. CNN reported: "Decision seen as victory for movie, recording industry" (Mears 2003). The problems refuse to go away, however, and in 2005, the U.S. Copyright Office undertook a full inquiry into the status of orphan works (www.copyright.gov/orphan/index.html). But the results offered little concrete in support of digital libraries. The Chronicle of Higher Education headline read: "Copyright Office Sides with Publishers in Proposal for Handling 'Orphan' Works"; the Copyright Office's recommendations were described as "unlikely to please archivists or scholars" (Foster 2006). Meanwhile, the Copyright Board of Canada has been operating a licensing system for orphan works since 1990 (www.cb-cda.gc.ca/unlocatable/index-e.html); fewer than 200 licenses have been requested, and most were granted.

In practice, it is much simpler for digital libraries to limit themselves to pre-1923 materials, to avoid having to identify rights-holders. Even when rights-holders can be traced, the digital library would have to negotiate for rights, a lengthy, expensive, and often fruitless process. Covey (2005) discusses acquiring copyright permission to digitize and provide open access to books. A possible

solution would be to operate within the "fair use" provisions of U.S. copyright law. These provisions might be invoked when a nonprofit library or archive makes materials available for research and private study. The legal situation is complex, and the institution should emphasize that it does not condone further distribution, such as commercial use or print publication. Relevant disclaimers can be seen on many digital library sites. See, for example, the Library of Congress (www.loc.gov/homepage/legal.html) or Duke University's Rare Book, Manuscript, and Special Collections Library (<http://scriptorium.lib.duke.edu/copyright.html>).

Contracts between freelance authors and newspapers or magazines did not, until recently, mention the right to disseminate their work via databases. This market was nonexistent in the pre-electronic age. The Supreme Court in 2001 handed down the *Tasini* decision (*New York Times* 2001), which recognized that these authors had rights in this area. Dissemination via a database, in which materials could be consulted individually, was considered separate from print or microfilm publication. As a result, the *New York Times* was said to have removed 115,000 articles by 27,000 writers from its database (Stern 2001). Since the mid-1990s, newspaper and journal publishers retain digital rights over freelance articles.

When copyrighted materials have been posted to the Internet, there must be a mechanism to remove them, either against a formal demand made under the Digital Millennium Copyright Act or an informal request. "Take down" or "cease and desist" orders are rarely invoked against digital libraries, which offer mainly cultural and historical materials. Authors are, in effect, asking to be removed from the historical record. Search engines are more likely to receive "cease and desist" orders; see the Chilling Effects Clearinghouse (www.chillingeffects.org) for sample demands.

A possible solution for digital libraries is to work with copyright-free materials. Southern Methodist University mounted a digital library of government publications from World War II (<http://worldwar2.smu.edu>); this is legal because there is no copyright on U.S. government publications. The National Library of Medicine maintains PubMed, disseminating over 17 million items of medical literature (www.ncbi.nlm.nih.gov/entrez/query.fcgi). There are no copyright restrictions here, because the system delivers abstracts, rather than full text.

Interesting new possibilities are presented by open licensing systems, such as Creative Commons (<http://creativecommons.org>); works subject to this license can be made freely available, but attribution can be required, commercial use can be prohibited, and the original creator can insist that derivative works must also be publicly available. The license relieves authors of liability or implication of warranties and is in many ways similar to open-source licensing in the software area. In November 2005, Google Advanced Search began to permit users to limit their searches to items that could be freely used or shared.

Selection of Materials for Digital Libraries

For an overview of the problems of selecting research materials for digitization, see Hazen, Horrell, and

Merrill-Oldham (1998). Their first criterion is, unsurprisingly, copyright. Next, they recommend carefully analyzing the intellectual content of the resources, and estimating current and potential use. This permits the definition of the nature and format of the digital product. Metadata must be created and delivered alongside the digital images, while archival copies must be carefully preserved. It is also important to examine the relationship to other digitization projects; finally, costs and benefits need to be carefully weighed. Projects that score well on these considerations should receive priority. Chowdhury and Chowdhury dedicate a chapter of their *Introduction to Digital Libraries* to "Collection Management" (2003, 89–102).

Digitization of Materials for Digital Libraries

The classic method of offering access to individual visual resources, such as photographs, posters, or drawings, is by a series of three images. A high-quality archive image is produced on a scanner; this is then used to create an access or working image for use by the general public. The third image is a small thumbnail, used for quick reference (Boss 2001; Lee 2001). These terms are described in more detail below.

Archive Image

This is a high-quality image that was scanned directly from the original; it is normal to use an uncompressed TIFF (tagged image file format) for this purpose. This system preserves high-quality images; a resolution of 600 dpi (dots per inch) is commonly adopted. The archive image has significant value, because scanning is an expensive procedure, which may subject the originals to damage; it will therefore be carefully preserved. All digitization procedures must produce archive images, but these are often not available to the end user. TIFF files occupy significant space on servers and can be slow to download. An additional consideration is that some digital libraries will wish to profit from selling their own prints of quality images. For a discussion of the technical standards adopted in the digital imaging of photographic collections, see Frey (1997).

Access Image or Working Image

This must be adequate for a consultation by serious users. It is normal to use a high-quality JPG (Joint Photographic Experts Group) image, which is generated from the archival TIFF. JPG files offer quality spatial and color reproduction, and a high compression ratio; they are in wide use on the Internet. A digital library may, for instance, generate JPG images at a resolution of 300 dpi and a size of 640 × 480 pixels.

Thumbnail Image

This gives the user a quick preliminary overview of the access image. Thumbnails are typically produced as a medium- or low-quality JPG, about one-tenth of the size of the access image, at a resolution of 72 dpi. Alternatively, thumbnails can be generated using GIF (graphic interchange format) files.

Practitioners in this area offer detailed advice; see *Digital Projects Guidelines* from Arizona State Library,

Archives and Public Records (<http://www.lib.az.us/digitalProjectsGuidelines.pdf>), or the *Western States Digital Imaging Best Practices* from the Colorado Digitization Program (www.cdphheritage.org/digital/scanning/documents/WSDIBP_v1.pdf); both of these include useful summary tables. See also Washington State Library's *Digital Best Practices* (<http://digitalwa.statelibrary.gov/newsite/best.htm>), *Moving Theory into Practice: Digital Imaging Tutorial* from Cornell University Library (www.library.cornell.edu/preservation/tutorial/index.html), and *Benchmark for the Faithful Reproduction of Monographs and Serials* from the Digital Library Federation (www.diglib.org/standards/bmarkfin.htm). The *Image Quality Calculator* from the Digital Services Development Unit of the University of Illinois at Urbana-Champaign permits calculation of file sizes and recommended resolutions for a wide range of materials (<http://images.library.uiuc.edu/projects/calculator>). For a comparative discussion of file types for images, audio, video, etc., see the *University of Virginia Community Digitization Guidelines*, from the University of Virginia Library (www.lib.virginia.edu/digital/reports/uva_digitization_guidelines.pdf).

Further standardization and development can be expected in this field; notably, there is increasing interest in a major upgrade of the original JPG format, known as JPEG 2000 (www.jpeg.org/jpeg2000/index.html). JPEG 2000 images offer high quality and excellent compression; they are gaining acceptance for video reproduction and could possibly displace TIFFs for the archiving of still images. They use various file extensions—for example, .jp2, .jpx, .jpc. Sending the first part of a JPEG 2000 file can result in a version similar to the original .jpg; continuing to transmit the file results in the fidelity improving until the original image is restored. For a comprehensive account, see Acharya and Tsai (2005). OCLC has made available an extension to CONTENTdm digital library software, facilitating the viewing of JPEG 2000 images (www.oclc.org/news/announcements/announcement139.htm).

Low-value books may be disbound and the pages stack-fed through a scanner. But this process may take longer than anticipated, because of the dust generated by the paper, and will almost certainly render the original unusable. Rare materials, older books, and fragile items cannot be disbound and will demand gentle handling. The newest development is automated digitization machines, which carefully turn pages of books and even of newspaper volumes. 4DigitalBooks (www.4digitalbooks.com; Figures 11 and 12) offers equipment approximately the size of a sports utility vehicle that can now process up to 1800 pages an hour. This Swiss-designed robot is considered cost-effective for projects that involve more than 5.5 million pages (Markoff 2003).

For a smaller automated digitizer, based on a system developed by Xerox, see Kirtas Technologies (www.kirtas-tech.com; Figure 13). An animated graphic of their page-turning system can be seen on their home page. They claim that their page-turning process is more gentle than the human hand and can process 1200 pages per hour. Kirtas equipment is also being used in the Open Content Alliance digitization initiative (Quint 2005).

When digital libraries offer textual content, they need to convert page images to text that can be indexed

Figure 11: Automated digitizer, developed by 4DigitalBooks; illustration from www.4digitalbooks.com/photogallery/photo0001.jpg

Figure 12: Close-up of the automated digitizer, from 4DigitalBooks; illustration from www.4digitalbooks.com/photogallery/152_5300_b.jpg

and manipulated. Some early systems, such as Project Gutenberg, began by offering plain ASCII text files, which were keyboarded by hand. It is now normal to present HTML text that has been generated by OCR (optical character recognition) software. Relevant OCR products include OmniPage Pro from Nuance (www.nuance.com), formerly ScanSoft, or the Russian ABBYY

(www.abbyy.com). Even the best scanning software can sometimes confuse certain terms; for example, modern/modern or clean/dean. Digital libraries face special difficulties. They strive to offer accurate conversion, but they handle large numbers of old and specialized books, which include antique fonts, unusual spellings, rare terms, and soiled pages. For a general discussion

Figure 13: Automated digitizer, developed by Kirtas Technologies; illustration from www.kirtas-tech.com/APT_1200/productphotos.asp

of these problems, see the text-scanning helpsheet from the University of Virginia (<http://etext.lib.virginia.edu/services/helpsheets/scan/scantext.html>). Text destined for digital libraries must be carefully proofread, but this requires qualified and dedicated personnel. Project Gutenberg has developed a system whereby new text is proofread page by page, by teams of volunteers (www.pgdp.net/c/default.php).

In order to guarantee textual integrity to the user, it is common for digital libraries to offer two versions of a text: page image and HTML. The image can be a medium-quality JPG; this is often adequate for plain text, without illustrations. An alternative is to offer the text in portable document format (PDF). This generally gives satisfactory results, and the images accurately represent the original. It is possible to include security measures—for example, to inhibit printing—and most Internet users are familiar with the free Adobe Reader. An archival version of PDF, known as PDF/A, is being developed by the International Standards Organization (www.digitalpreservation.gov/formats/fdd/fdd000125.shtml). Both text and page-image formats are available in digital libraries such as the University of Michigan's *Making of America* (<http://quod.lib.umich.edu/m/moagrp>). Here, users have a choice of image, text, or .pdf files, which can be presented in normal, large, or small size. The *Digital Quaker Collection* (<http://esr.earlham.edu/dqc>) offers full text and page images

of more than 500 seventeenth- and eighteenth-century Quaker texts.

Software for Digital Libraries

Standard HTML can be used to hand code small-scale digital collections. Major systems can use commercial enterprise-level software, such as Oracle, used for the New York Public Library Digital Gallery (<http://digitalgallery.nypl.org/nypldigital/dgabout.cfm>). But it is now common to adopt software specifically designed for digital libraries for digital library development. Principal options, in alphabetical order, are:

CONTENTdm: Digital Collection Management Software is rapidly gaining ground as a high-performance storage and retrieval system for multimedia cultural collections (<http://www.oclc.org/contentdm>). Originally developed at the University of Washington, CONTENTdm was acquired in 2006 by OCLC, the major supplier of cataloging data to libraries (www.oclc.org). Numerous cultural collections have already adopted CONTENTdm (<http://contentdm.com/customers/index.html>); typical users include the Louisiana Digital Library (<http://louisdl.louislibraries.org>) and the American Indians of the Pacific Northwest Collection at the University of Washington Libraries (<http://content.lib.washington.edu/aipnw/index.html>).

DigiTool: This is an enterprise solution for the management of digital assets in libraries and academic environments, enabling institutions to create, manage, preserve, and share locally administered digital collections, such as institutional repositories, collections of educational materials, and special collections (www.exlibrisgroup.com/digitool.htm). It is used by the Digital Library Center at the Florida State University Libraries (<http://digitool3.lib.fsu.edu>). DigiTool is part the Ex Libris library automation software suite, internationally known for its multilingual and multiscript capacity (www.exlibrisgroup.com).

DLXS: This was developed by the University of Michigan Digital Library eXtension Service; its strength is in the indexing and presentation of multi-page documents (www.dlxs.org). It was used for the approximately 10,000 books and 50,000 journal articles of the University of Michigan's *Making of America* collection, mentioned above (<http://quod.lib.umich.edu/m/moagrp>). An additional 3000 books are available in the *Wright American Fiction Collection, 1851–1875* (www.lettrs.indiana.edu/web/w/wright2).

DSpace: This captures, stores, indexes, distributes, and preserves digital research materials for academic institutions (<http://dspace.org>). A joint project of MIT Libraries and Hewlett-Packard, the original DSpace can be searched at <https://dspace.mit.edu/index.jsp>; PDF is used for full-text documents. DSpace is an open-source software that can be downloaded from <http://sourceforge.net/projects/dspace> (Atwood 2002).

eXist: This is an open-source XML database system from Germany (<http://exist.sourceforge.net> or <http://exist-db.org>). It was used for a major database of historical documents, *The Proceedings of the Old Bailey, 1674 to 1834* (www.oldbaileyonline.org). These describe more than 100,000 criminal trials held at London's central criminal court; it is probably the largest collection of historical texts relating to the lives of ordinary people.

Greenstone Digital Library: This software is an open-source system for building and distributing digital library collections (www.greenstone.org). It automatically generates organized digital collections and gives them a standard interface; full text indexes and lists of titles are created automatically (Witten and Bainbridge 2002). It is capable of handling large document collections, in various formats, and functions at server or desktop level. It will even export to CD-ROMs and can handle a variety of languages and scripts, including Arabic and Chinese. It was developed in New Zealand at the University of Waikato, and was used for the *New Zealand Digital Library* (www.nzdl.org; Figure 14), which offers significant United Nations and humanitarian collections. Greenstone is distributed under the GNU Public License, and can be downloaded freely from www.greenstone.org/cgi-bin/library?a=p&p=download.

Hyperion Digital Media Archive: This offers full-text indexing, storing, and accessing of nonbook materials in digital form (www.sirsi.com/Sirsiproduts/hyperion.html). It is a product of SirsiDynix, an Alabama conglomerate, a

Figure 14: Opening screen of the New Zealand Digital Library, created using Greenstone open-source software

major supplier of automated systems to libraries. For an example, see the Hekman Digital Archive at Calvin College in Grand Rapids, Michigan (www.calvin.edu/library/researchhelp/hda).

Insight: This is an image management and delivery software from Luna Imaging, produced in collaboration with the J. Paul Getty Trust, California, and Eastman Kodak (www.luna-imaging.com). It is noted for the high quality of its images and its powerful zoom capacity; it is generally used for photographs, maps, and art objects. For sample collections, see www.luna-imaging.com/community/collectionsharing.html. One collection, the *David Rumsey Historical Map Collection* (www.davidrumsey.com), won a Webby Award in 2002; it features nearly 16,000 maps.

Olive ActivePaper: This archive software creates fully searchable collections of historical newspapers, which can be scanned from the original or from microfilm. Readers can click on any item in the newspaper, such as an article or advertisement; this is enlarged in a separate window. For an example, see the *Pennsylvania Civil War Newspapers* at Penn State University (<http://digitalnewspapers.libraries.psu.edu/Archive/Skins/civilwar/welcome.asp>). Olive Software is widely used by newspapers, magazines, and libraries (www.olivesoftware.com).

Open-source software is frequently used for server-site software, especially in academic environments. It has, therefore, found applications in the digital library area. For a discussion of open-source software for the management of digital content, see Zhang and Gourley (2003). SQL (structured query language) is the best-known database

language; in digital library applications, it is normally used via open-source serverside software, such as PostgreSQL or MySQL. Combinations of MySQL with PHP have also been found to be valuable. PHP (www.php.net) can be described as a serverside Web-scripting language that can easily interface with MySQL via a predefined function set. Another alternative is Macromedia's ColdFusion (<http://www.adobe.com/products/coldfusion>). The *Digital Library Toolkit* (Noerr 2003) offers a general review of software for the area. For a discussion of digital workflow management, with a diagram, see Choudhury and colleagues (2000). People working on projects that involve querying traditional library catalogs will wish to adopt software compliant with the Z39.50 standard, which permits Boolean searching and truncation. A resource center for this standard is maintained by the Library of Congress (www.loc.gov/z3950/agency).

Metadata and Digital Libraries

The value of digital objects is significantly increased by the addition of metadata, or subject terms and descriptive elements characterizing the digital object. Figure 15, from the *LOUISiana Digital Library* (<http://louisdl.louislibraries.org>) demonstrates the value of metadata.

The metadata elements locate the photograph geographically, define its subject, identify the photographer, and give additional information. What might have been simply an attractive photograph becomes a resource that researchers can identify and retrieve. Note that metadata is hyperlinked; users who wish to examine other illustrations of wrought iron can jump directly to them.

Figure 15: Photograph of a building in the French Quarter of New Orleans, digitized by the LOUISiana Digital Library, with metadata

It is possible to distinguish various types of metadata:

Descriptive Metadata: Author, title, abstract, subject headings, and so forth; the data used to index, discover, and identify digital resources.

Structural Metadata: Structural metadata include the structural divisions of a resource (i.e., the chapters of a book) or sub-object relationships (such as the individual diary entries in a diary). This is used to record information on the internal organization of the digital resource; it permits navigation within the resource, and display of specific digital objects.

Administrative Metadata: Management information for the digital object, such as the information needed to access and display the resource; this might include technical information, such as the hardware and software used in producing the image, the resolution at which the image was scanned, compression information, pixel dimensions, and so forth (Dublin Core 2005, 6). Technical metadata must be recorded accurately and consistently to ensure that the image files remain usable well into the future; standards are currently being developed (www.niso.org/committees/committee_ae.html). Digital rights management information, such as contact information and rules for appropriate use of the data, is another important element of administrative metadata. Correct legal language must be employed to specify digital rights.

Metadata can be:

- embedded within the resource to which it relates; for example, as HTML metatags
- stored in a data management database separate from, but linked to the resource
- included in a resource discovery service, such as a library catalogue, with a link to the resource (National Library of Australia 2002).

Vellucci (1998) prepared an in-depth discussion of metadata for the *Annual Review of Information Science and Technology*. Traditional archive or library systems can include entire collections of photographs, listed on a single catalog or container record. Digital presentation, however, will require the application of detailed metadata. The Dublin Core is the best-known metadata system; it was specifically developed for digital environments at a 1995 meeting in Dublin, Ohio. The Dublin Core metadata element set (<http://dublincore.org/documents/dces/>) specifies metadata elements such as title, creator, subject, date, and format; it also includes digital rights management information. Dublin Core metadata best practices have been published by the Collaborative Digitization Program (Dublin Core 2005). Metadata are applied by professionals known as metadata analysts, who normally work with a list of acceptable terms. Established sources include *The Art and Architecture Thesaurus Online* from the Getty Museum (www.getty.edu/research/conducting_research/vocabularies/aat) and the *Thesaurus for Graphic Materials*, from the Library of Congress Prints and Photographs Division (www.loc.gov/rr/print/tgm1). The *Library*

of Congress Subject Headings are firmly established in traditional libraries and have been widely used in digital environments, such as the *American Memory* collections. Metadata analysts must avoid inconsistent vocabulary and take care with locally created terms, so as to maximize retrieval. Metadata creation adds significantly to both the value and the cost of systems; good metadata may be responsible for half or more of project costs. Metadata can facilitate retrieval of resources by major search engines, permitting the contents of digital libraries to be easily accessed by a wide audience, instead of becoming lost in the “deep Web” or “invisible Web.”

The Open Archives Initiative (OAI; www.openarchives.org) makes metadata widely available in digital environments. This is based on harvester/server architecture: participating data repositories make metadata available in standardized format; information systems harvest the metadata automatically and use it to power subject gateways. For an outline of the origins and development of the OAI, see Digital Library Federation (2001) or Lagoze and Van de Sompel (2001). OAI harvesting from the *NASA Technical Reports Server* (<http://ntrs.nasa.gov>) is described by Nelson and colleagues (2003). An important initiative is OAIster, from the University of Michigan, which is a sophisticated search interface to a variety of freely available, academically oriented digital resources (<http://oai.umd.umich.edu/oai/>). OAIster indexes more than 12 million items from more than 850 institutions. A registry of OAI providers is available from the Grainger Engineering Library, University of Illinois at Urbana-Champaign (<http://gita.grainger.uiuc.edu/registry/searchform.asp>). Kepler (<http://kepler.cs.odu.edu>) permits research teams or individual researchers to easily self-archive their own publications within an OAI-compliant digital library framework.

Indexing and Retrieval in Digital Libraries

Digital library users normally have a choice between browse and search access. Browse access, or directory-based access, offers a menu of choices, such as alphabetically organized lists of titles or authors, or lists categorized by subject, location, etc. Broad subjects can be subdivided by using nesting menus. This is simple to organize, even by manual procedures, and is typically offered by digital libraries from the opening page. Search access is via a search box, which permits the user to query an index generated by specialized software. Search boxes are prominent features of digital libraries, and can be quite sophisticated. For an example of a retrieval system with multiple boxes, see Gallica, the digital library of the National Library of France (<http://gallica.bnf.fr>; Figure 16). In this case, browsing by alphabetical subject terms is also available from the search page.

Word-by-word text indexing is one of the most valuable features of digital libraries. Specialized software includes the XPAT search engine, part of the University of Michigan Digital Library eXtension Service (DLXS) system (www.dlxs.org). For a working example, on a large file, see the Legacy National Tobacco Documents Library (LNTDL); this collection of more than 7 million documents, relating to the manufacture and marketing of cigarettes, was

Figure 16: Search boxes on Gallica, digital library of the National Library of France

Figure 17: Opening screen of the Legacy Tobacco Documents Library, from the University of California, San Francisco

obtained through legal discovery in relation to a lawsuit (<http://legacy.library.ucsf.edu>; Figure 17).

Simple Web Indexing System for Humans—Enhanced (SWISH-E; <http://swish-e.org>) is an open-source software that enables full-text indexing. It can be seen in use at many locations, including the Berkeley Digital Library SunSITE (<http://sunsite.berkeley.edu/cgi-bin/search.pl>), and the Apache Web server site (<http://search.apache.org>). An additional option is WebGlimpse (<http://webglimpse.net>), originally developed at the University of Arizona. A free version is available for educational or U.S. government users; it can be seen in the index to the papers of President George Bush, Senior (<http://bushlibrary.tamu.edu/research/paper.html>; test with “saddam”). Fluid Dynamics Software (www.xav.com/scripts/search) is widely used; for example, see the

Encyclopedia Titanica (www.encyclopedia-titanica.org/index.php), a fascinating collection of documents relating to the sinking of the Titanic. Indexing software from Master.com (www.master.com/texis/master/app/home.html) offers advanced Boolean search (AND, OR, NOT) capability; for a relevant example, see the Chicago Women’s Liberation Union (<http://cwlulherstory.master.com/texis/master/search/?q=CWLU&s=SS&cmd=Options>). MG is a freely available, open-source full-text retrieval system developed by the team responsible for the Greenstone library software (Witten, Moffat, and Bell 1999). It makes efficient use of disk resources by storing the index, and the text that is indexed, in compressed form (www.nzdl.org/html/mg.html). The Apache Lucene open-source Java text search engine (<http://lucene.apache.org/java/docs/index.html>) is used to power the DSpace digital

Figure 18: Concordance of the 100 most frequently used words in *Moby Dick*, generated by Amazon.com

repository system (www.dspace.org/technology/system-docs/functional.html).

Amazon.com (www.amazon.com) has recently been experimenting with the in-depth indexing of the books they have digitized. They automatically generate “statistically improbable phrases” or SIPs, the most distinctive phrases in the book; SIPs for Herman Melville’s *Moby Dick* include “pagan harpooners” and “ivory leg.” The “Capitalized Phrases” or CAPs, are people, places, events, or important topics frequently mentioned in the text; examples from *Moby Dick* include “Captain Peleg” and “Cape Horn.” They also generate concordances of the 100 most frequently used words in a book; Figure 18 shows an Amazon.com display of the concordance for *Moby Dick*.

Networking and Digital Libraries

Networking is a common feature in digital libraries, Borbinha and Delgado (1996) discuss the concept in general and point out the potential of the networked digital library to not only function as an information repository, but to become an active partner of the researcher, stimulating, supporting, and registering the process of the creation of knowledge. Fox and Marchionini (1998) expand the concept to a world-wide level, where barriers to interoperability and multilingual processing are being gradually overcome. The result will be the creation of a digital library system that can contribute significantly to global understanding and cooperation. A distributed digital library model, in which materials on separate machines are connected via a network, is frequently adopted (Adams, Jansen, and Howard 1998).

Networking of this type is a common feature in digital libraries, although it is often done in a manner not immediately perceptible by users. Probably the best-known examples of networked digital library collections are those produced for the American Memory as a collaborative effort between the Library of Congress and major libraries,

historical societies, and similar institutions. This program lasted from 1996 to 1999, and was known as the Library of Congress/Ameritech National Digital Library Competition (<http://memory.loc.gov/ammem/award/online.html>). For a typical example, see “The Chinese in California, 1850–1925” (<http://memory.loc.gov/ammem/award99/cubhtml>; Figure 19).

The initial page (Figure 19) clearly acknowledges that the “materials in this online compilation are drawn from collections at The Bancroft Library, University of California, Berkeley, The Ethnic Studies Library, University of California, Berkeley, and the California Historical Society, San Francisco.” The file is on a server at <http://memory.loc.gov>.

Figure 20 shows a thumbnail image and metadata from that collection; this is still on the Library of Congress server. The working or access image (Figure 21), however, is held on a server at the University of California, Berkeley. The system is fully networked, but functions so smoothly that few users will notice the change of server.

Networking features are very obvious to the users of PictureAustralia, maintained by the National Library of Australia (www.pictureaustralia.org/index.html). The initial page (Figure 22) is very clear: “Search for people, places, and events in the collections of libraries, museums, galleries, archives, universities, and other cultural agencies, in Australia and abroad - all at the same time. View the originals on the member agency web sites and order quality prints.” The initial page welcomes new participants, and includes a link for those who would like to make their picture collections available through PictureAustralia. (It is also interesting to note the disclaimer typical of Australian image collections: “Indigenous Australians are advised that PictureAustralia may include images or names of people now deceased.”).

Search results come from a wide range of libraries. Figure 23 shows hits from the State Library of Victoria, the State Library of Queensland, the State Library of

Figure 19: Opening screen of the Chinese in California collection, from the Library of Congress

Figure 20: Thumbnail and meta-data for an image in the Chinese in California collection, from the Library of Congress

New South Wales, Logan City Council Libraries, and the Australian Heritage Photo Library.

It is possible to see metadata of specific items by following the link to “More information” (Figure 24).

A link from the “More information” page takes the user to the original image; in this example, it is held on the server of the State Library of Queensland (Figure 25).

Witten, McNab, Jones, and colleagues (1999) discuss the sophisticated distributed digital library system set up for the New Zealand Digital Library (www.nzdl.org). This covers twenty collections that use different indexing and browsing structures, can be accessed by computers in different locations, can accept queries in various languages, and contain text, images, and audio.

Figure 21: Working or access image from the Chinese in California collection. This image is held on the server of the University of California, Berkeley.

Figure 22: Initial page of PictureAustralia, from the National Library of Australia

The use of mirror sites constitutes a common alternative form of networking to digital libraries; they reduce load on the central server, and the existence of multiple sites offers increased data security. Project Gutenberg (www.gutenberg.org/wiki/Main_Page) is widely mirrored and offers a page of instructions on how to set up a mirror site (www.gutenberg.org/wiki/Gutenberg:Mirroring_How-To). A static IP address and a T1 network connection are minimum requirements; Project Gutenberg occupies 150 GB, a total of 100,000 files in twenty-three formats. Mirrors are expected to update files nightly; forty sites

currently mirror Project Gutenberg (www.gutenberg.org/MIRRORS.ALL). The New Zealand Digital Library (www.nzdl.org) is mirrored by the Southern Alberta Digital Library Centre, at the University of Lethbridge (www.sadl.uleth.ca/gsdll/cgi-bin/library). Attempts to link from North America to www.nzdl.org are automatically redirected to www.sadl.uleth.ca. The Perseus Digital Library of classical literature (www.perseus.tufts.edu) is based at Tufts University, Somerville, Massachusetts, but is mirrored in Chicago and Berlin. WiderNet (www.widernet.org), based at the University of Iowa, offers a creative solution for

Figure 23: Search results from PictureAustralia, from the National Library of Australia

Figure 24: Thumbnail image and metadata from PictureAustralia, from the National Library of Australia

locations in Africa and elsewhere that suffer chronic connectivity problems. This is the eGranary Digital Library Appliance, a server preloaded with over 5 million relevant documents, which can be slotted into any local area network (www.widernet.org/digitalLibrary/index.htm). This can be searched like the Internet and offers Lucene indexing; there is also 20 GB for local documentation, which is indexed alongside the preloaded documents.

MAINTAINING DIGITAL LIBRARIES

Security and Digital Libraries

Digital libraries offer a valuable contribution to document security because they generate and disseminate multiple copies; experience has shown that documents available in numerous copies are more likely to survive.

Figure 25: Full-size image, held on the server of the State Library of Queensland

Security problems during digitization are similar to those that occur during microfilming. Special care must be taken with old, fragile documents. It is normal to digitize valuable materials on site to avoid the risks of transportation. All items must be carefully counted and numbered before they are processed. Some projects have outsourced digitization to countries such as the Philippines or India, but this is possible only for materials that can be replaced.

Lesk's *Understanding Digital Libraries* devotes part of a chapter to security (Lesk 2005, 174–80); he discusses basic security, sensible administration, and the use of firewalls and passwords. Even digital libraries that make their materials publicly available will need to take precautions against hackers, crackers, or persons who attempt to download major proportions of their content. The materials within digital libraries constitute the best of an institution's resources. Older materials may be in the public domain and could possibly be redistributed. If users can steal an image, the institution may possibly lose publication fees.

Access-management policies must be established to determine who can access information, and under what terms and conditions. Access management is required because of copyright, trade secrets, obscenity, privacy, or donor restrictions. Commercial environments or secure government systems also require appropriate access formalities. It is common to restrict digital library materials to users of specific institutions; this is frequently achieved by Internet Protocol (IP) identification, which limits access to specific computers. An additional possibility is the use of passwords. Arms devotes a chapter of his textbook, *Digital Libraries*, to access management and security (Arms 2000, 123–42). Access management begins when users identify themselves; specific procedures then

validate the users, verifying their true identities. Digital resources also have to be authenticated, while specific categories of materials may require special restrictions.

So far, only one significant example of violation of an institutional digital library has come to light. 50,000 articles were illegally downloaded from *JSTOR* (www.jstor.org), the University of Michigan's scholarly journal archive, by an intruder who used a false IP address (Olsen 2003). *JSTOR* posted a strong statement concerning unauthorized access (www.jstor.org/about/unauthorized.html). It is also testing new open-source software, Shibboleth, which guarantees the security of online services and restricts access to digital content (<http://shibboleth.internet2.edu>). Shibboleth is being developed by Internet2 researchers with National Science Foundation support, and is being evaluated or adopted by numerous institutions. Systems such as Blackboard, Ebsco, Elsevier, OCLC, and Thomson Gale are now Shibboleth-enabled (<https://wiki.internet2.edu/confluence/display/seas/Home>).

Watermarks are used as a security measure for paper currency, and can also be incorporated in digital objects, in which a subsidiary visible image can be inserted in a protected image. Visible watermarks are in common use to mark sample images in catalogs of commercial photograph collections; see the *New York Times* (www.nytimes.com/ProdCode.aspx?prodcode=791; Figure 26) or Corbis (<http://pro.corbis.com>).

Herzberg (1998) discusses charging for content by digital libraries, analyzing a variety of different charging mechanisms, both existing and proposed. Credit-card payments are not appropriate for very small purchases, and advertising revenues are limited in the digital library area. It is also possible to sell subscriptions, but in practice few users are willing to subscribe, and fees have to be shared with middlemen. Considerable interest has been

Figure 26: This image of a facsimile Audubon print, offered for sale by the *New York Times*, has been protected by a clearly visible watermark. The print shows an American White Pelican

shown in micropayments, whose value is too small to justify the use of a credit card (e.g., less than one dollar). In theory, they are an attractive option, but their widespread use depends on mechanisms that can rapidly transfer small amounts of money at a low cost.

The other side of digital library security is the privacy of users. Sturges and colleagues (2003) point out that with digital technology, libraries can archive detailed information on users; this is normally considered confidential, but could be relevant for security, law enforcement, or commercial organizations. Saeednia (2000) examined problems of privacy and authentication in digital libraries, and proposed practical solutions, such as a key exchange protocol and an identification scheme, based on computing discrete logarithms and factoring large integers.

Preservation and Digital Libraries

Despite the fact that their major objective is to increase access, digital libraries also perform important preservation functions; for instance, they reduce the need to handle original resources. There are two related considerations: preservation of the original materials and preservation of the digital surrogates.

It is normal to retain the originals of photographs and broadsides, even after digitization. It can be more difficult to preserve books, which may be printed on

brittle paper and will possibly have been disbound to facilitate processing. Microfilm is sometimes seen as the solution for long-term preservation, but libraries have been roundly criticized for not preserving the originals of microfilmed newspapers (Baker 2001). Libraries will feel an obligation to preserve originals after digitization, especially when they are the last copies. Some difficult decisions will have to be made. Should the project include minor restoration, such as mending tears? Digital library projects rarely cover costs of restoration. Should images be processed to restore their original color? Normally, digitizers will aim to faithfully reproduce the object as it is now.

Protection of digital resources is equally essential in digital library management. Even when the public has access only to working JPG images, the system must guarantee the long-term storage of the high-quality archival images. Libraries traditionally think in terms of centuries, while computer software is frequently replaced, often by incompatible systems. This poses a risk to all types of digital information. File formats and versions constantly change, while hardware and software become obsolete; important data therefore becomes unusable. This process can affect even simple data formats and even high-quality information resources, such as databases and e-journals, can be jeopardized. When the problem is finally detected, it may be too late (Ray et al. 2002).

Arms devotes a chapter of his *Digital Libraries* to repositories and archives (Arms 2000, 245–62), in which he suggests criteria for the evaluation of repositories and the storage of metadata. He discusses digital archeology, which can be defined as recovering data from superseded systems, and views digital archival operations in terms of refreshing and migrating data. Arms distinguishes carefully between:

Migration: The “preservation of digital content, where the underlying information is retained but older formats and internal structures are replaced by newer,” and

Emulation: “[T]he replication of a computing system to process programs and data from an early system that is no longer available” (Arms 2000, 276–9).

The *Introduction to Digital Libraries* by Chowdhury and Chowdhury also includes a chapter on digital library archiving and preservation (2003, 214–26). Problems and strategies for digital preservation are outlined and principal projects in the area are discussed. For a general overview of preservation problems, see the discussion by Smith (2004), published by the Council on Library and Information Resources (CLIR). The fundamental questions of stewardship, such as which resources are to be collected and preserved, by whom, for how long, and for whom, have undergone a major change. We now face key questions such as, Is it possible or desirable to select or preserve the rapidly growing Web? Can institutions collaborate in collection development, the creation of metadata, or preservation activities? Can institutions, such as libraries, preserve digital information that is owned by commercial companies and licensed to the library? Who will be responsible for paying for the preservation of digital resources?

Gould and Ebdon (1999) surveyed the digitization and preservation policies of major libraries and archives worldwide. Of those that digitized materials, 64 percent had a preservation policy for digitized documents. The majority, 83 percent, allowed access to the original document after digitization, while 67 percent of the institutions surveyed stored their originals in special conditions. Just over half of the respondents had established a policy for migrating data to recent platforms; when migration was undertaken, all data were migrated. Data migration was never contracted out; it was always an internal activity. The survey was conducted for the International Federation of Library Associations (IFLA) and the United Nations Educational, Scientific and Cultural Organization (UNESCO).

The Digital Library SunSITE at Berkeley suggested four levels of collecting, each of which implied a different commitment to preservation:

Archived: The material is hosted here, and the library intends to keep the intellectual content of the material available on a permanent basis.

Served: The material resides here, but the library has not (yet) made the level of commitment to keeping it available that it has for “archived” materials.

Mirrored: A copy of material residing elsewhere is hosted here, and the library makes no commitment to archiving.

Also, an institution other than the library has primary responsibility for the content and its maintenance.

Linked: The material is hosted elsewhere and the library points to it at that location. Therefore, the library has no control over the information (<http://sunsite.berkeley.edu/Admin/collection.html>).

Material in any category except for the first, “Archived,” may be reallocated from one level to another to meet changing information needs, access to or responsiveness of remote servers, local demands, and so forth. Material designated as “Archived” cannot be downgraded. The Digital Library SunSITE at Berkeley also offers additional preservation resources at <http://sunsite.berkeley.edu/Preservation>.

Disaster protection in digital libraries is discussed by Tennant (2001). RAID (redundant array of inexpensive [or independent] disks) technology is commonly used. RAID level one involves mirroring data or making one complete copy; level five distributes data between several physical disks. Necessary infrastructure includes uninterruptible power supplies and fire and alarm systems. He also recommends backing up data to a distant location.

The National Digital Information Infrastructure and Preservation Program (NDIIPP), led by the Library of Congress, is actively developing an infrastructure for collecting and preserving digital resources (www.digital-preservation.gov). It is working with a variety of partners to collect and preserve specific types of digital content that will be used for generations to come. The National Library of Australia offers much valuable documentation on digital preservation at PADI: Preserving Access to Digital Information (www.nla.gov.au/padi). This covers strategies and standards, and links to a variety of relevant information sources. In the United States, the Online Computer Library Center (OCLC) maintains a digital archive that enables members to store digital assets, either item by item or as collections (www.oclc.org/digitalarchive/default.htm).

The Internet Archive and the Wayback Machine (www.archive.org; Figure 27) offer access to a wide variety of resources, and also permit surfing through Web pages from several years ago. Because they have an important role in the preservation of the Internet, it is relevant to discuss their archiving procedures. They operate on PCs with clusters of IDE (integrated device electronics) hard drives. For storage they use DLT (digital linear tape) and hard drives in various formats (www.archive.org/about/about.php). DLT is rated to last 30 years; for additional security, industry practice is to migrate data every decade. The Internet Archive, however, plans more frequent migrations. It also collects software and emulators that will assist future researchers and historians in analyzing the development of the Internet.

At a library level, copies of electronic journals can be automatically archived by LOCKSS, or Lots of Copies Keep Stuff Safe, from Stanford University (<http://lockss.stanford.edu/index.html>). This open-source system regularly polls the Web journals subscribed to by the library; new material is preserved in a local cache.

Figure 27: The Internet Archive and the Wayback Machine

It is possible to find resources that represent the same document at different sites. Digital library professionals must therefore concern themselves with the authenticity of their digital resources. For a discussion of this problem, see Bearman and Trant (1998). As part of this process, it is essential to be able to analyze the methods used to digitize the original, and to be able to determine the integrity of a specific digital copy.

The archival TIFF files that digital libraries produce directly from original resources must be carefully preserved; at the moment they are frequently archived on sets of CD-Rs. A relatively small digital library can easily be responsible for more than a thousand CD-Rs. For a comprehensive guide to the handling of CDs and DVDs by librarians and archivists, see Byers (2003), which covers the types of media used, and their manufacture, care, and operation, with special attention to their longevity and conditions of storage. Digital libraries typically use “write-once” CD-Rs to record digital data; these should survive for at least a century if correctly stored. CD-Rs and DVD-Rs incorporate silver, silver alloy, or gold reflective layers; gold lasts longer, but is also more expensive (Byers 2003, 10). The problems are much more serious with mass-produced audio CDs, which use aluminum reflective layers; these may last for only twenty years, even when carefully looked after. The problem recently came to the attention of a wide public when an enthusiast noted that 15 to 20 percent of his audio CDs would not play because of “CD rot” (Baig 2004). The Library of Congress’s Preservation Research and Testing Division is actively engaged in this area (Library of Congress 2003). Even when preservation is guaranteed, a digital library will often possess thousands of CD-Rs; numbering and file naming rules will have to be drawn up, so that specific images can be easily retrieved.

The basis of book preservation has always been the legal deposit of copies at national libraries; this concept is gradually being applied to digital resources. UNESCO

issued an important *Draft Charter on the Preservation of the Digital Heritage* (UNESCO 2003). Member nations need to create appropriate legal and institutional machinery to secure and preserve their digital heritage. Key elements of national preservation policy are legal or voluntary deposit in libraries, archives, and similar repositories. Adequate access to digital heritage materials that have been legally deposited should be ensured. Appropriate legal and technical structures must be established to guarantee authenticity and prevent manipulation of digital resources. The British Library has begun a project that may eventually lead to the archiving of all U.K. Web sites (Marson 2004). The U.K. Web Archiving Consortium, led by the British Library, and including the National Archives and the Scottish and Welsh national libraries, has processed more than a thousand British Web sites for preservation (<http://info.webarchive.org.uk/index.html>). The British Library does not censor the materials; ultimately, it aims to archive all British Web sites. The software used for the archiving system was developed by PANDORA (Preserving and Accessing Networked Documentary Resources of Australia), established by the National Library of Australia in 1996 (<http://pandora.nla.gov.au/index.html>). PANDORA now covers nearly 15,000 Web sites. Because of the lack of legal deposit provisions covering online publications in Australia, PANDORA seeks permission from publishers before including materials in the Archive (<http://pandora.nla.gov.au/legaldeposit.html>). In a wider initiative, the National Library of Australia contracted the Internet Archive to harvest the entire Australian Web domain for six weeks during June and July 2005; 185 million unique documents were archived from more than 800,000 hosts. Because Australia lacks legal deposit provisions for online materials, it is still uncertain what access can be provided to this collection (<http://pandora.nla.gov.au/panfaqs.html>). It is interesting to compare digital and audio materials in this context: the United States introduced legal deposit for sound recordings only in the

1970s; as a result, many early recordings are not in the Library of Congress (Lesk 2005, 240).

Continuity of Digital Libraries

The existence of “dead links” is a common problem on the Internet, of special concern to digital libraries that link to outside materials. Links need to be checked frequently, and dead links have to be updated or removed. A possible solution is offered by persistent identifiers, PURLs or persistent URLs (<http://purl.oclc.org>). To a user, a PURL looks and works just like a URL, but it does not point to an Internet page, but to an intermediate service. This PURL resolution service switches the client seamlessly to the current URL. The most widely established identification system for individual digital library items is the digital object identifier (DOI; www.doi.org/index.html). A DOI persistently identifies a content-bearing entity in a digital environment, permitting localization, links between users and content suppliers, and management of intellectual property rights. The DOI will remain the same even if the object’s network location changes. The standard DOI format is “DOI:Prefix/Suffix”; for example: “DOI:10.1045/june2003-paskin,” where the prefix, “DOI:10.1045” indicates a DOI issued by *D-Lib Magazine*. That journal is responsible for the suffix, which identifies a June 2003 article by Norman Paskin, the director of the International DOI Foundation (Paskin 2003). A search engine, such as Google, can use the DOI to retrieve the paper. CrossRef, the official DOI registration agency for scholarly and professional publications (www.crossref.org), has registered over 20 million DOIs (CrossRef 2006). The OpenURL standard uses Web-transportable packages of metadata to switch users to relevant versions of digital materials (www.niso.org/committees/committee_ax.html); for instance, a user who retrieves an article citation can obtain immediate access to the “most appropriate” copy of that object via a linking service (www.exlibrisgroup.com/sfx_openurl.htm).

Digital libraries have a short history and are frequently established by solid institutions, such as universities. Most of the systems implanted are apparently still functioning. Notess (2005) lists more than twenty dead search engines, but there is no list of dead digital libraries. The few closures that have come to public attention all seem related to changes in government policies. PubScience (formerly at <http://pubsci.osti.gov>) enabled researchers to examine more than a thousand peer-reviewed journals free of charge through a single interface. It was part of the U.S. Department of Energy’s Office of Scientific and Technical Information, but was closed because it duplicated commercial services (Foster 2002). Government policies also had a major impact on the ERIC database (www.eric.ed.gov). This collection of 1.2 million documents and journal articles on educational topics has established itself as a primary source since its foundation in 1966. In 2003–2004, it was heavily modified; the previous model, based on decentralized clearinghouses, was abandoned in favor of a centralized system (Viadero 2004). A chain of pioneering virtual hospitals was managed from the University of Iowa for many years (www.vh.org or www.vh.org/pediatric/index.html); content was

either contributed by faculty of the University of Iowa or taken from U.S. government or other noncopyrighted sources. The system was supported by U.S. Navy funding for the parallel Virtual Naval Hospital, but this funding was withdrawn at the beginning of 2006 (www.vnh.org). The virtual hospitals continue to exist, but only in highly truncated form.

Sustainability is frequently discussed in the digital library field, where it covers a variety of topics, from the technical problems of digital preservation, to the social impact of long-term accessibility of resources (McArthur 2003). The Framework of Guidance for Building Good Digital Collections, developed by the National Information Standards Organization (NISO) states as the third principle of successful collection building that “A collection should be sustainable over time. In particular, digital collections built with special internal or external funding should have a plan for their continued usability beyond the funded period” (www.niso.org/framework/Framework2.html). Funding proposals submitted to the Institute for Museum and Library Services (IMLS) typically include sustainability; for an example, see *Connecticut History Online* (<http://www.cthistoryonline.org/cdm-cho/cho/project/IMLSproposal.htm#sustainability>).

CONCLUSION—THE FUTURE OF DIGITAL LIBRARIES

The future of digital libraries seems assured. They offer a series of advantages in relation to traditional libraries: it is not necessary to travel to a library to access information; two or more people can access the same item simultaneously; they are available beyond the often restricted opening hours of traditional libraries; digital texts can easily be copied, updated, corrected, and even manipulated when copyright permits; they can also be indexed word-for-word; older, rarer materials can be made available, and repeatedly examined, without risk to the originals; and links to related materials can easily be established (McCarthy 2004). Traditional libraries cannot easily compete on any of these features.

Like any new technology, digital libraries do have constraints and limitations. A seminal paper by Lynch (2001) drew attention to the potentially significant social cost of digital technologies, which permit increased levels of monitoring and control. The use of digital books can be regulated in a manner that would be totally impossible with traditional books. At the same time, unless publishers are able to establish levels of control that they consider appropriate, they will not permit in-print texts to move to digital form. Migration of this nature has been notably slow up until now. An increase has been noted in e-book sales (Becker 2004), but the process continues to be slow because of the traditional and decentralized nature of the publishing business. While publishers hesitate, they risk being sidelined by new entrants to the digital arena. Over the past year or so, major digitally based initiatives such as Google, Yahoo!, and MSN have begun to pay significant attention to book digitization. Early activities have been hindered by a lack of standardization and clear business models, but players of this importance

can be expected to invest significantly in the solution to these problems. It is probable, therefore, that large-scale book digitization activities will have a major impact in the near future.

The relationship between traditional and digital libraries will also become more clearly defined in the future. How far will digital libraries be linked with or integrated into library cataloging systems? It is necessary to remember that libraries face several digital challenges at the same time: digital libraries, online article databases, federated searching, link resolvers, and other systems; it is uncertain exactly how digital libraries will work within a larger library automation structure.

Even more exciting developments can be expected from the impact on digital libraries of the latest trends in Internet technology. The small orange buttons that denote RSS (really simple syndication) feeds are now common on dynamic Web sites and are beginning to turn up in digital libraries such as ibiblio (www.ibiblio.org/rss/ibiblio.rss), the Internet Archive (www.archive.org/services/collection-rss.php), and Project Gutenberg (www.gutenberg.org/feeds/today.rss). PubMed (www.ncbi.nlm.nih.gov/entrez/query.fcgi?DB=pubmed) now permits users to create personalized RSS feeds for medical literature (www.nlm.nih.gov/pubs/techbull/mj05/mj05_rss.html). Personalization is also occurring in other digital library applications. The British Library's Online Gallery permits sending e-cards with illustrations from the library's collections (www.bl.uk/ecards/index.html). The ingenious system offers 30,000 images from Britain's Science Museum and other museums (www.ingenious.org.uk); free registration permits users to save images, send e-cards, and create Web galleries. The updated version of the ERIC Educational Resources Information Center (www.eric.ed.gov) permits users, after free registration, to save searches and search results, and to submit documents for possible inclusion in the database. I have already noted the collaboration between the National Library of Australia's image-sharing system, PictureAustralia (www.pictureaustralia.org), and the Flickr photo-sharing system (www.flickr.com), which is part of Yahoo! Flickr permits users to load their own materials, leave comments about the photographs of others, and report abuse of the system. O'Reilly (2005) discusses the concept of Web 2.0 systems such as Flickr, which are based on sharing, tagging, reputation, and trust. Of interest to the digital library field are sites like YouTube (www.youtube.com), a video-sharing system, or Digg (www.digg.com), for distribution of technical news; both of these permit participants to vote dynamically for or to promote specific items. Another technology central to Web 2.0 is peer-to-peer distribution, which has had a major impact on popular systems, and has been adopted as the basis for the European Commission's BRICKS: Building Resources for Integrated Cultural Knowledge Services project (www.brickscollaboration.org). Web 2.0 services may well have a significant future impact on digital libraries.

At the moment, readers view e-text on devices they already have: desktop PCs, laptops, or personal digital assistants (PDAs). The desktop area has been fairly stable recently, but there have been many major changes in the area of small electronic devices. Cell phones are daily becoming more powerful, and the iPod was transformed

from a novelty into an everyday object in a couple of years. The author expects that the convergence between a cut-down laptop and an improved iPod will shortly produce a universal digital tool that will also serve as a widely acceptable platform for text. Kurzweil's seminal book, *The Age of Spiritual Machines*, forecast that printed books and paper documents would become rare by the year 2019, and that all multimedia and documents would be fully digitized by 2029 (Kurzweil 1999). The role of libraries will, no doubt, be to continue to guarantee access to quality and older materials. Institutions such as libraries and archives have contributed much in the past decade toward the digitization of cultural materials. This is an important step toward achieving a major medium-term objective of humanity, the digitization of the cultural heritage of civilization.

GLOSSARY

American Memory: The Historical Collections of the National Digital Library, maintained by the Library of Congress (<http://memory.loc.gov>); one of the world's largest digital libraries, with more than 100 collections, a total of 9 million digital items, including photographs, manuscripts, rare books, maps, sound recordings, and moving pictures.

Digital Library: "A managed collection of information, with associated services, where the information is stored in digital formats . . . organized on computers and available over a network, with procedures to select the materials in the collections, to organize it, to make it available to users, and to archive it" (Arms 2000, 2).

Digital Preservation: Process of guaranteeing the long-term preservation of digital objects, by storage of files in secure repositories, migration to other platforms, and other means.

Digital Rights Management: Procedures that ensure that holders of digital rights are clearly identified and receive the stipulated payment for their materials; they may also impose additional restrictions on use of digital objects—for example, inhibiting printing or prohibiting further distribution.

Digitization: Process of converting analog documents (such as paper, photographs, film, maps) to digital form.

Electronic Journals (E-Journals): Journals, such as scientific and professional journals, available in digital form.

Electronic Theses and Dissertations (ETDs): Theses and dissertations available in digital form.

Indexing: The process of systematically generating pointers or keys to the content of texts, permitting readers to go directly to locations that contain specific words or deal with specific topics.

Metadata: Data about data. Keys, guides, or indications of the content of a document or data set and stipulations of appropriate use.

Migration: Transfer of digital data from one format or platform to another; normally, digital data are migrated from an older format or platform to a newer format or platform, to guarantee preservation.

Multimedia Digital Library: Digital library that delivers content in a variety of formats: text, photographic images, audio, short films, and so forth.

Project Gutenberg: One of the longest-running digital libraries (http://www.gutenberg.org/wiki/Main_Page), founded in 1971. It has always concentrated on simple, copyright-free texts that can be read on almost any computing platform. Now offers more than 20,000 texts and is supported by a network of mirror sites.

Sustainability: The capacity of a digital system to continue operating for the foreseeable future. Sustainability depends on factors such as organizational or governmental commitment, a secure financial model, adequate protection from external attack, use of appropriate formats and platforms, and collections that are of lasting interest or are capable of being updated.

INTRODUCTION

To a large extent, distance learning derives its ability to exist as a recognized form of educational delivery from the technologies it uses. When print packages and postal services were the predominant technologies, distance learning was often referred to as “correspondence study,” in which teaching and learning consisted of tutors and students exchanging instructional packages and completed assignments through the mail. With the current set of sophisticated information and communication technologies (ICT), distance learning is increasingly referred to as “e-learning.” Teaching and learning activities regularly include lectures, whole-group discussions, small-group collaborative activities, mentoring relationships between students and their advisors, and informal chats among students and instructors. In the inaugural issue of the *Journal of Distance Education*, several authors identified computer conferencing as the harbinger of these profound changes.

Since text-based, asynchronous, computer conferencing was introduced to distance learning settings in the mid-1980s, many innovations have surpassed its sophistication (e.g., blogs, wiki, podcasts, Web-based audio conferencing and videoconferencing); still, computer conferencing retains a central position in distance education, while newer innovations continue to remain marginalized. Students, instructors, administrators, and learning theorists each find in it unique advantages; however, it is its ability to provide communication that removes access barriers (e.g., temporal, geographical, situational) in a manner that is generally considered cost-effective for students, instructors, and institutions—as well as being transparent and ubiquitous.

In addition to being cost-effective (unlike older models of audio conferencing and videoconferencing) and easy to use (unlike many newer innovations), computer conferencing provides mediated interaction (unlike paper-based correspondence). It is this last element (mediated communication) that is central to providing an effective

learning environment and the focus of our discussion. In particular, computer conferencing enables students to interact with each other and their instructor, but it does not force them to be at a particular place at a particular time; it allows instructors to incorporate discussion in their courses, but in a way that allows participants to deliberate over others’ opinions, reflect on their own, and articulate cogent responses. It supports many-to-many communication, but it is inexpensive and simple for people to master.

In this chapter, we discuss the presence of computer conferencing and its ability to provide mediated interaction in distance learning. Our practice and our research are situated in higher education settings, and our discussion will reflect this perspective. We begin with definitions of our key terms and then move to a historical approach to understanding computer conferencing’s position in distance learning. This approach provides a rich context for discussions of the learning theories, instructional activities, and proposed outcomes that are associated with computer conferencing in distance learning. We also provide substantial attention to empirical studies that have investigated each of these topics. A historical approach, we feel, provides some unique insights into an area that has been the subject of excellent reviews, including definitive reviews by Romiszowski and Mason (2004, 1996).

DEFINITIONS

Computer Conferencing

For the participants in distance learning, *computer conferencing* is a sort of robust e-mail that facilitates textual, asynchronous, group communication. By *textual*, we mean that message production is limited to the characters on a computer keyboard, and by *asynchronous* we mean that the communication is somewhat liberated from the temporal and orchestral constraints of face-to-face communication. It is one tool among a set that

tutors, course designers, and students encounter in their learning management systems (e.g., Blackboard, Moodle, WebCT). In taxonomies of educational technologies, it is grouped in the category of computer-mediated communication systems, along with synchronous chat systems, listservs, bulletin board systems, e-mail, desktop videoconferencing, and voice over Internet protocol systems (VoIP). Those who have studied and worked in the field of distance learning for years regard it as one of three forms of conferencing that also include audio conferencing and videoconferencing. Others position it as the fulcrum on which distance learning rises from its second generation to its third—from learners as consumers of packaged media (e.g., print, audio tapes, and videotapes) to learners as participants in interactive media (Nipper 1989). These are some of the meanings of computer conferencing in the context of distance learning.

Distance Learning

Distance learning too has an assortment of meanings, but each overlaps to some extent with Keegan's (1990) definition of *distance education*. Seeking to delimit the field, Keegan compiled the following parameters that set distance education off from on-campus education and further distinguished it from what many saw as related activities such as continuing education or informal learning:

Distance education is a form of education characterized by a) the quasi-permanent separation of teacher and learner throughout the length of the learning process, b) the influence of an educational organization, c) the use of technical media, d) the provision of two way communication, and e) the quasi-permanent absence of the learning group throughout the length of the learning process. (Keegan 1990, 44)

As is predictable in a field involving ICT, this definition was being undermined before it made it to print—largely by computer conferencing. Soon, all that remained of Keegan's essences were items b and c (i.e., the influence of an educational organization and the use of technical media).

Even the term *education* was proving to be a moving target. Simultaneous with the growing presence of ICT in the field, a pedagogical movement was afoot that regarded the term *education* with disapproval. Bringing together themes from progressive education, humanistic psychology, andragogy, and cognitive and social constructivism, many argued that the very term *education* linguistically positioned instructors and content at the center of education, a position that rightly should be occupied by students and learning. Distance educators responded to this discourse, and *distance education* became, for many, *distance learning*.

After losing three of Keegan's five essences, and then the term *education*, the concept *distance* became a focus of dispute. Moore (1972) deconstructed the term *distance*, questioning whether geographic separation had any influence on learning, and whether the real distance—the psychological, social, and cognitive separation between students

and instructors—was any less salient in, for instance, the large lecture halls of conventional universities.

After much reflection and dialogue, the contours of the field, which we refer to as *distance learning* in the rest of this chapter, are probably less certain than they were before Keegan attempted to consolidate the field, which coincided with the introduction of the disruptive technology, computer conferencing.

HISTORY OF MEDIATED INTERACTION IN DISTANCE EDUCATION

To appreciate the role of mediated interaction via computer conferencing in distance learning, it is helpful to know something about the history of this union. In this section, we examine the ways in which this technology has been construed in the distance learning literature. We provide brief sketches of the views of Holmberg (1983), Moore (1991, 1983, 1972), Garrison, Anderson, and Archer (2001, 2000), Laurillard (2002), Evans and Nation (1989), Gunawardena, Lowe, and Anderson (1997), and Murphy (2004, 2003). Although there are others who have made important contributions to computer conferencing, these theorists have made the most significant contributions within the field of distance learning. From their writings, we abstract the learning activities and educational outcomes they associate with mediated interaction, and the larger theoretical frameworks they draw on to work out a role for computer conferencing in distance learning.

Holmberg and the Guided Didactic Conversation

One of the first to conceive of a role for interaction in distance learning was Holmberg (1983). He began writing in what is now referred to as the first generation of distance education (Nipper 1989), the era of correspondence study. Apropos of this system, Holmberg understood learning as "primarily an individual activity" (p. 116). Despite this understanding and the rudimentary communication technologies available to distance learning at the time (e.g., print packages, telephones, and postal services), he was already considering a role for interaction among students and members of the supporting educational institution.

Holmberg (1983) identified two forms of interaction that would be helpful to students studying at a distance. The first he characterized as *real*, in which conversational partners included students and members of the supporting institution. This type of conversation was realized when students submitted assignments and received feedback from their tutor. Because it was one of the few avenues of interaction available to distance learners, Holmberg urged that student assessment should be more like a conversation than an examination, and students' submissions, therefore, should be treated as a springboard for prescriptive feedback, not simply grading.

Holmberg (1983) characterized the second form of interaction as *simulated*, in which the conversational partners were the students' existing knowledge, the new course content, and the voice of the tutor that was becoming increasingly internalized. To facilitate this type

of interaction, Holmberg suggested that course material be composed in an accessible, exoteric tone rather than the esoteric tone typical of scholarly texts.

He envisioned three outcomes arising from, in his terms, “guided didactic conversations.” The first was improved retention of information (he wrote specifically of recall and recognition). A second, higher-level outcome would be the students’ ability to weigh new information, to consider it, and to think critically about it. A third outcome also central in Holmberg’s theory were the feelings of study pleasure and motivation that would arise as students developed personal relationships with members of the supporting institution.

The theoretical links between these educational outcomes and the literal and figurative forms of interaction can be found in the cognitive, humanistic, and sociocultural psychology movements that were influencing education at the time. Cognitive psychologists, building on the work of Piaget (1977), were arguing for the importance of interaction among peers and adults in generating the perturbation necessary for intellectual development (Perret-Clairmont, Perret, and Bell 1989). Sociocultural psychologists were advancing notions of *thinking* as an internalized conversation with the generalized other (Vygotsky 1984), and humanistic psychologists were stressing the importance of a warm, receptive, supportive environment for learning (Rogers and Freiberg 1993).

In 1983, Holmberg reviewed a set of studies that tested several conjectures emanating from his theory. His summary of the results was pessimistic, “The investigations,” he concluded, “cannot be said to have given any conclusive evidence in favor of my hypotheses” (p. 34). Garrison (2000) has offered a similar evaluation of Holmberg’s theory, in which he suggests that the results are an inherent aspect of correspondence study and its associated media and communicative processes:

The question arises as to whether an inert learning package, regardless of how well it is written, is a sufficient substitute for real sustained communication with the teacher as both content and learning expert. The role of the teacher was largely simulated by way of written instructions and commentary. In sum, the organizational assumptions and principles of the industrial model and the dependence upon written communication seriously constrain and limit the role of conversation and the full emergence of a transactional perspective. (Garrison 2000, 29)

In Garrison’s larger discussion, and in several other analyses, the assessment that emerges of Holmberg’s ideas is that they were sound, but unable to be realized because of the constraints of the technology and the modes of distance learning. The communicative learning activities, the educational outcomes, and the role of mediated interaction that he envisioned were prescient. Each continues to be represented prominently, in modern forms, in current research on computer conferencing. Several researchers continue to demonstrate that: (a) for many students, peer communication makes distance learning more enjoyable; (b) the interaction among students,

instructors, and peers can foster critical, reflective thinking; and (c) acculturation to a discipline can be enhanced by interaction in computer conferencing.

Moore and Dialogue

Moore (1991, 1983, 1973) was influenced by the North American andragogical movement in adult education (e.g., Knowles 1990). Premised on a few of the central tenets of andragogy, such as the assumptions that adults are autonomous and self-directed learners, Moore developed a model of interaction in distance settings. Whereas Holmberg’s model arose in the context of correspondence study, Moore’s, with its central positioning of two-way communication technologies, was reflective of a second- or third-generation model (Nipper 1989). An additional distinction between Moore’s and Holmberg’s models is that the latter was constrained by convention and by technology to figurative uses of the term *conversation*, whereas Moore began formulating a literal conceptualization of the role of dialogue in distance education.

To Holmberg’s (1983) two forms of interaction (learner-to-content and learner-to-tutor), Moore (1983) added a third—learner-to-learner. Unfortunately, Moore is vague about the specific types of interaction that count as *dialogue* between learners. In 1991, Moore offered the following explanation in a review of his model:

Dialogue describes the interaction between the teacher and learner when one gives instruction and the other responds. The extent and nature of this dialogue is determined by the educational philosophy of the individual or group responsible for the design of the course, by the personalities of teacher and learner, by the subject matter of the course, and by environmental factors. (p. 3)

Subsequent studies of his model have been equally equivocal. Chen and Willits (1999) studied Moore’s three forms of interaction without providing an operational definition of dialogue, and Haughey and Fenwick (1996) studied the construct *participation*, which colloquially seems to signify something different than dialogue. Saba and Schearer’s (1994) substantive study of Moore’s theory included the following definition of *dialogue*: “the extent to which, in any educational program, learner and educator are able to respond to each other” (p. 42).

More recently, research by Kanuka, Collett, and Caswell (2002) sought to gain a greater understanding of the topics of feedback, emotional distance, and structure using the two dimensions within the theory of transactional distance (structure and dialogue, and autonomy). *Dialogue* was defined as the interaction between the instructor and learners with computer conferencing as the communication medium. The results of this study revealed that most instructors and students continue to experience a tension between structure, dialogue, and autonomy. However, how these issues should be addressed depends on the characteristics of the learners. Their findings showed that if learners are autonomous, they will tolerate emotional distance and be less dependent on feedback, and a high level of transactional distance is fine; if learners are not

autonomous, a low level of transactional distance is most appropriate. Thus, using this rationale, the results of this study indicate that there is a need for instructors to assess learner autonomy. In keeping with Moore's theory, if the learners are not autonomous, then instructors will need to address the issues of feedback, emotional distance, and structure.

These findings support Moore's (1983) theory that dialogue, when defined as interaction with computer conferencing between the instructor and students, could close the *transactional distance*, which he defined as the subjective feeling students have of the social, psychological, and cognitive separation from their teacher and the subject matter. Moore's goal was to deconstruct unfavorable comparisons between distance education and face-to-face education. In a phenomenological vein (though he does not use this term), Moore argued that a student's experience of distance was more important than an objective assessment of geographic separation.

Andragogy, a perspective of adult learning first articulated by Knowles (1990), plays an important role in Moore's thinking. Synthesizing motifs from humanistic psychology with the unique situation of mature students, Knowles formulated a perspective on how best to assist adults in their efforts toward continuing education. Moore saw a fortuitous relationship between Knowles' notion of learner-centeredness and distance education. Unlike immature learners, adults can independently assess gaps in their current knowledge, identify resources that will fill these gaps, motivate themselves to progress through difficult material, and evaluate their progress toward a learning goal. This construction of autonomous, independent students looking to formal education as a resource for their self-directed efforts was congenial to the form of education offered at a distance.

Moore's theory has been subjected to two systematic empirical tests. Using the path analysis technique, Saba and Shearer (1994) found that dialogue was inversely related to transactional distance. Chen and Willits (1998) studied a course delivered via interactive television and found that in-class discussion contributed to student achievement. The relationship, however, is complex. Some students report that student-to-student interactions are not critical to their success and are the least important form of interaction (Kelsey and D'souza 2005). The instructor that Kelsey and D'souza interviewed mused: "To be honest, my feeling was that distance students really didn't want contact and were not interested in communicating" (p. 36). Gorsky, Caspi, and Tuvi-Arad (2004) studied the role of learner-to-learner and learner-to-instructor dialogue in distance education using naturalistic methods. When an online forum was available but not required, they found that students contacted one another only when they experienced conceptual difficulties. They concluded, "Theories like Moore's often assign to interpersonal dialogue an importance that may not be realized in practice" (p. 17).

Garrison and the Community of Inquiry

Garrison (1997) moved the discourse begun by Holmberg (1983) and Moore (1983) squarely into the third generation

of distance education, the era in which information and communication technologies (ICT) became commonplace. He was one of the first to begin writing specifically about computer conferencing and its role in distance education. Like Moore, his focus was on adult learners. But more like Holmberg, he was skeptical about the level of independence and self-directedness that one should expect of students. Garrison adopted Moore's concern with several configurations of learner, content, and instructor interaction.

It was with authors such as Garrison, Anderson, and Archer (2001, 2000) that constructs such as Holmberg's *conversation* or Moore's *dialogue* began to take on a specific definition in terms of its observable, constituent, conversational actions. Garrison et al. proposed a four-phase process for online discussion and identified conversational actions characteristic of each phase. The phases and processes include:

Triggering Event: Presenting background information that culminates in a question

Exploration: Presenting opinions, sharing anecdotes, contradicting previous ideas

Integration: Building on others' ideas, articulating evidentiary hypotheses

Resolution: Applying knowledge, testing and defending solutions

Garrison et al. caution that this is an idealized sequence, and that actual discussions are less formalized.

Critical thinking and higher-order learning have preoccupied Garrison's writing throughout his career, and it is these outcomes that he associates with computer conferencing's role in distance learning. He and his colleagues define critical thinking as "the acquisition of deep and meaningful understanding as well as content-specific critical inquiry abilities, skills, and dispositions" (Garrison et al. 2000, 4). The way to achieve these goals with computer conferencing they wrote is through *critical discourse*:

For a computer conference to serve as an educational environment, it must be more than undirected, unreflective, random exchanges and dumps of opinion. Higher-order learning requires systematic and sustained critical discourse where dissonance and problems are resolved through exploration, integration, and testing. (p. 21)

Garrison has identified critical thinking as the hallmark of higher education, and he sees critical discourse in computer conferencing as a way to enact this in distance-learning settings.

Resonating in Garrison et al.'s (2001, 2000) model is the sociocognitive account of learning that originated with Piaget (1977) and was developed further by European researchers including Perret-Clairmont et al. (1989). Essentially, Garrison et al. envisioned student's unreflective assumptions and inchoate ideas becoming clear, precise, and defensible through antagonistic interaction

with other students and their instructor in computer conferences. This is an important departure from Holmberg (1983) and Moore (1983, 1972), who envisioned mediated conversations or dialogues leading to increased study pleasure, motivation, engagement, and thereby achievement.

Like Holmberg's (1983) and Moore's (1983) models, Garrison et al.'s (2001, 2000) model has generated much interest, and is currently used extensively as a theoretical framework for research in the field of distance learning. However, there are few empirical tests of its central claims. Garrison has participated in three studies, and there have been others that explore the relationships he envisioned (Garrison and Cleveland-Innes 2005; Garrison, Cleveland-Innes, and Fung 2004; Garrison et al. 2001; Kanuka, Rourke, and Laflamme 2006; Vaughan and Garrison 2005). Consistent in these studies is the following problem: researchers are unable to assess the relationship between critical discourse and critical thinking because of the virtual absence of critical discourse. Garrison et al.'s (2001) own findings are representative. Summarizing their analysis of a graduate level computer conference, they report:

The highest frequency (42%) of contributions to the conference was categorized as *exploration*, the brainstorming phase where people share information. The frequency of the contributions fell-off rapidly at the next stage, *integration* (13%). This issue is worthy of special consideration. There was a virtual absence of responses (4%) associated with the highest phase of critical discourse, *resolution*. (p. 6)

Observers of interaction as it takes shape in computer conferencing rarely report significant instances of critical discourse, dissenting opinion, challenges to others, or expressions of difference. This makes it difficult to assess the relationship between the types of discursive activity promoted by Garrison et al. (2000) and their hypothesized outcomes.

Laurillard and the Conversational Framework

Laurillard (2002) is another writer who proposes a role for mediated discussion, supported by computer conferencing, in distance learning. Like Holmberg (1983), her use of the term *conversation* is both literal and figurative. In its literal sense, *conversation* connotes the verbal interaction that students have with each other and with their tutors. In its figurative sense, *conversation* connotes a type of educational cybernetics.

The relevant notion of cybernetics is that existing actions are perfected based on the continuous assessment of their current state versus a goal state. Pask (1976) saw in this process an analogue to the coaching that takes place between an adult and a child. Building on these ideas, Pask devised a *conversational theory* of education, which, though complex and dotted with neologisms, can be conveyed as follows. First, a subject-matter expert devises a detailed conceptual map of a topic. Next, he or she (or it—computer-assisted instruction is quite suitable in this

function) presents this representation to students. Students then acquire this representation and demonstrate the accuracy of their acquisition through assessment.

With minor variations, this is the model that Laurillard (2002) uses to understand the role of computer conferencing in higher education. Her general model positions the tutor and the student in an adaptive relationship. Tutors and students exchange their understandings of course topics, and during these exchanges, tutors tailor their authoritative, expert presentations to the students' existing constructions. The students modify their constructions so that they become successively more accurate representations of the tutors' (Allan 2004; Hannon 2002; Laurillard 2002). There are also opportunities for self-assessment as students articulate and argue their interpretations with their peers. These are presented as secondary in importance however, with Laurillard worrying about students "floundering in mutually progressive ignorance" (1993, 172).

Unfortunately, Laurillard (2002) has not conducted empirical studies of computer conferencing. Her empirical work focuses mainly on videodisk technology, with the bulk of her writing being of a reflective sort. Allan (2004), however, has also argued that adaptive feedback from a perceptive tutor will always be more effective than the best artificial-intelligence tutors: "No simulation or technology is able to give truly intrinsic or fully customized feedback," she declares. "Online tests, self-assessment questions, and other artificial sources of formative feedback cannot provide the degree of depth or insight required for customized learning assistance in the ways a human tutor can" (p. 11). Rowntree (1997) adds, "Personal feedback is the key to quality in education and training. It is what enables us all to learn from our experience. A response from another human being that challenges or confirms our understanding, helps us overcome errors, and encourages us toward new insights" (p. 58). Hannon's (2002) research suggests that feedback is also related to student satisfaction: "Students want (and expect) quick and detailed responses to their questions and concerns, as well as timely, qualitative feedback on their work" she concluded:

Students in distance learning courses apparently expect active interaction with their teachers. Students who felt that these expectations were met tended to be positive about the course, and about distance learning in general. These expectations can be time consuming for professors and teaching assistants to meet, but there are possible compromises that will satisfy both teachers and students, such as posting ideal responses to exam questions and using a course listserv to answer common questions. Student and faculty evaluations of more recent versions of the online courses reveal that these measures have improved satisfaction with distance learning for both parties. (Hannon 2002, 42)

Although the specifics of Laurillard's model have not been investigated empirically, there is support for the principles on which it is based, and it has been highly

influential within the field of distance learning literature and research.

Gunawardena, Lowe, and Anderson and Meaning Making

Gunawardena worked through several of the models we have described in order to understand the role of computer conferencing in the distance learning courses she taught. From her practical perspective, she encountered difficulties with each of the models: Either they presented ambiguous conceptualizations of interaction that were difficult to implement as an instructor, or they were rooted in teacher-centered, instructivist perspectives of education (Gunawardena, Carabajal, and Lowe 2000). To address these limitations Gunawardena et al. (1997) developed their own model. Like Garrison et al.'s (2000) and Laurillard's (2002) models, it arose at a time when conferencing was widespread, and it found an audience for whom the distinction between distance learning and on-campus education was beginning to blur.

Gunawardena et al. (1997) believed that computer conferencing should be used to engage students in five types of conversational activities. The activities occur in a developmental sequence and move students through a five phase process of knowledge co-construction:

- Sharing and comparing information
- Discovering and exploring dissonance
- Negotiating meaning
- Testing new knowledge
- Establishing a consensus and applying knowledge

Unlike the models described previously, the space between these conversational actions and the purported learning outcomes does not present a large and inferential gap. Through conversation with their peers and the instructor, students will build networks for subsequent collaboration, enhance the information provided in course materials with additional information and alternative interpretations, and make the topics personally meaningful.

This model reflects a social constructivist understanding of learning and instruction. Koschmann and colleagues (1996) describe the role of computer conferencing in the social constructivist models:

It is in the process of articulating, reflecting and negotiating that we engage in a meaning making or knowledge construction process. This process can become even more powerful when communication among peers is done in written form, because writing, done without the immediate feedback of another person as in oral communication, requires a fuller elaboration in order to successfully convey meaning. (p. 83)

With its foundation in social constructivism, Gunawardena et al.'s model of computer conferencing is notably different from the previous models. Gunawardena et al.'s (1997) model, like the others we have reviewed, has received little

empirical substantiation. When studies are conducted, a familiar problem reappears: conference participants rarely engage in anything beyond the lowest levels of interaction (i.e., sharing-and-comparing information). The elements of discussion that are essential to meaning making and knowledge construction—elements such as exploring dissonance and negotiating meaning with peers and the instructor—are absent. Gunawardena et al. (2001) summarize the results of several applications of the model:

As the model has been applied to a succession of conferences, it has brought to light indications that many, probably most, conferences do not proceed beyond the lowest phases of knowledge co-construction. Participants share and compare their experiences and viewpoints on course topics but when they find areas of disagreement, instead of negotiating meaning as the social constructivist theory would suggest, they appear to agree to disagree. (p. 8)

One of the studies that Gunawardena et al. are referring to may have been Kanuka and Anderson's (1997), in which the authors report:

Evidence from surveys, telephone interviews, and transcript analysis indicates that most of the interaction is of a sharing and comparing nature. Dissonance and inconsistency are not actively explored, there is little testing of evidence against experience or the literature, and rarely do participants state the relevance or application of new knowledge that might have been created. (p. 45)

In a similar study of computer conferencing in an undergraduate setting, Thomas (2002) reports:

The quality of interaction was insufficient to promote the levels of interpersonal communication necessary for a truly conversational mode of learning. While there was evidence of some interaction with students building upon or presenting arguments against other students' contributions, there was no real co-operative development of ideas between groups of students. (p. 359)

De Laat (2001) found similar results in her content analysis of an online discussion. Using Gunawardena et al.'s (1997) interaction analysis scheme, she found many initiations to which there were no replies. Gunawardena et al. (2001) observed that dissonance and the testing and modification of proposed co-constructions were almost absent in the conferences that she studied. Further substantiation of these results are provided by Davis and Rouzie (2002), Pena-Shaff and Nicholls (2004), and Yakimovicz and Murphy (1995), among others.

Murphy and Solving Problems in Collaborative Environments (SPICE)

Murphy (2000) developed a model of computer conferencing that, like that of Gunawardena et al. (1997), presents

an alternative to the teacher-centered, instructivist perspective of teaching and learning in distance settings. Murphy stipulates a specific learning activity for which conferencing should be used. As we have in previous sections, we will describe that activity, the types of outcomes with which it is associated, Murphy's account of the relationship between the activities and outcomes, and the empirical evidence that she and her colleagues have brought to bear on the model.

Murphy (2000) regards computer conferencing as a medium that allows students studying at a distance to engage in purposive, collaborative activities, namely, problem solving. She envisions group problem solving as occurring in a developmental sequence that begins with superficial interaction and culminates in the production of a shared artifact. Murphy has identified six stages in this sequence and a corollary set of conversational actions for each stage (Murphy 2004, 2000). They are:

Social presence: Sharing personal information, complimenting others, expressing appreciation

Articulating individual perspectives: Stating personal opinions, summarizing/reporting on content

Accommodating others' perspectives: Challenging others' statements

Co-constructing meaning: Seeking clarification/elaboration, responding to questions

Building shared goals and purposes: Proposing a shared goal, working toward a shared goal

Producing shared artifacts: Producing a document or other artifact collaboratively

Murphy sees the strength of computer conferencing as a forum in which students can debate, wrestle, and argue with each other over individual interpretations. However, she is aware of the virtual absence of these processes in most instances of conferencing. That is why she introduces collaborative problem solving as an essential activity for computer conferencing. Where others assumed that any type of interaction in an asynchronous, textual environment would automatically be valuable, Murphy argues that small group, collaborative problem-solving activities compel students to contend with each other's opinions and interpretations.

A strength of Murphy's model is the sustained program of empirical study that informs her conceptual framework and her claims about computer conferencing. In a series of projects, she has examined the validity of her conceptualization of the problem-formation/problem-resolution process, the validity of the instrument used to assess students' engagement in the six-stage process, and the students' experience of the learning activity (Murphy 2004, 2003, 2000). The results of the empirical investigations support the findings of Garrison et al. (2001), Gunawardena et al. (1997), Kanuka and Anderson (1997), and others who have looked for the social construction of knowledge in computer conferencing. Murphy (2004) summarizes these results:

Students engage primarily in processes related to *social presence* and *articulating individual*

perspectives and do not reach a stage of sharing goals and producing shared artefacts. Few messages show evidence of collaborative processes such as *accommodating others' perspectives*, *reflecting others' perspectives*, or *co-constructing shared perspectives and meanings*. Still fewer messages show any attempt to *build shared goals and purposes*, and no messages show evidence of *producing shared artifacts*. (pp. 427–8)

Empirical observations of computer conferencing in distance learning consistently find a predominance of monologues, relational communication, or superficial interaction and a meager amount of collaboration and knowledge co-construction. Murphy hypothesized that a learning activity that compels students to interact in meaningful ways—collaborative problem solving—would change this; however, she has found little evidence to support this hypothesis so far.

In 1992, Mason called on distance educators to develop a conceptual and empirical rationale to guide the use of computer conferencing in distance learning, and since that time there has been a proliferation of models. The models we have reviewed represent important developments in the conceptualization of the role of computer conferencing in distance learning. Our review has certainly not been exhaustive. We have excluded some notable efforts that have been reviewed extensively in the literature and whose principles have been incorporated into the models we did review.

DISCUSSION

Many models for the role of computer conferencing in distance learning have been developed. Table 1 provides an overview of the most noteworthy models described in this chapter. Upon examination of the types of learning activities and educational outcomes prescribed in these models, we can see that they can be grouped into two broad categories: (1) Dialectical models, in which computer conferencing is regarded as a forum in which students engage in critical discourse and thereby critical thinking, and (2) dialogical models in which students engage in collaborative meaning making and thereby social knowledge construction. Unfortunately, both models are more successful at prescribing what teachers and students should or might do than they are at describing what they actually do. Neither set of models receives consistent support in systematic observations of students and instructors.

Of collaborative meaning making, Pena-Shaff and Nicholls (2004) provide the following evaluation:

Conversations online are more like people standing up and taking the floor one by one and speaking as long as they want. Whoever speaks next may talk about anything. It is like conversing in soliloquies or, in centuries past, through letters carried by horse and driver to distant colonies. Others have little influence on one's thoughts at the time of writing. (p. 257)

Table 1: Noteworthy Contributions to Models of Computer Conferencing in Distance Education

Theorist	Theory	Brief Description
B. Holmberg	Guided didactic conversation	One of the first to theorize a role for interaction of distance education Proposed two forms of interaction: <i>Real</i> conversations (learner to tutor) <i>Simulated</i> conversation (learner to content)
M. G. Moore	Theory of interaction	Proposed that three forms of interaction should be present in distance education for effective learning: Learner-learner Learner-content Learner-tutor/teacher
D. R. Garrison T. Anderson W. Archer	Community of inquiry	Some of the first theorists to specifically write about the use of computer conferencing in distance education Proposed a four-phase process of critical discourse in computer conferencing as necessary to enact critical thinking skills. The phases are as follows: <i>Triggering Event</i> : presenting background information that culminates in a question <i>Exploration</i> : Presenting opinions, sharing anecdotes, contradicting previous ideas <i>Integration</i> : Building on others' ideas, articulating evidentiary hypotheses <i>Resolution</i> : Applying knowledge, testing and defending solutions.
D. Laurillard	Conversational framework	Developed a model for effective computer conferencing as being: <i>Discursive</i> : There needs to be some dialogue between the learner and instructor about why the topic is important <i>Adaptive</i> : The instructor must be prepared to shift the focus to reflect how the learners are doing <i>Interactive</i> : Learners must engage in the topic at a practical level and receive feedback on their actions <i>Reflective</i> : Learners must connect the feedback they received from their actions back to the topic and articulate it back to the instructor in an essay or project of some kind exhibiting their new understanding
C. Gunawardena C. Lowe T. Anderson	Model for meaning making	One of the first models proposed in distance education using computer conferencing based on social constructivism. This model proposed five phases of knowledge co-construction: Sharing and comparing information Discovering and exploring dissonance Negotiating meaning Testing new knowledge Establishing a consensus and applying knowledge
E. Murphy	Solving problems in collaborative environments (SPICE)	Identified six stages of group problem solving that occur in sequence, and a corollary set of conversational actions for each stage: <i>Social presence</i> : sharing personal information, complimenting others, expressing appreciation <i>Articulating individual perspectives</i> : stating personal opinions, summarizing/reporting on content <i>Accommodating others' perspectives</i> : challenging others' statements <i>Co-constructing meaning</i> : seeking clarification/elaboration, responding to questions <i>Building shared goals and purposes</i> : proposing a shared goal, working toward a shared goal <i>Producing shared artifacts</i> : producing a document or other artifact collaboratively

Of critical discourse, Marttunen (1998) provides this assessment:

Results reveal that the majority of students' messages are non-interactive in nature. In particular, real interaction, including responses to responses, is very rare. In addition, interaction between students turns out to be mainly non-argumentative in nature: only a small percentage of students' references to each others' texts express opinions opposed to those of fellow students, and only a smaller fraction indicate grounded disagreement. The results suggest that the pedagogical aim of our studies, to engage students in argumentative interaction, is not realized very well. (p. 397)

Fortunately, solutions are arising among the dozens of researchers who have recorded similar observations. The first of three that we will discuss is discussion facilitation.

The role of a facilitator in an online discussion is perhaps the most written about topic in this domain. Dozens of authors have studied and written about the roles and responsibilities of a successful facilitator (Berge 2002; Garrison et al. 2000; Heimstra 1994; Paulson 1995; Salmon 2000; Shea, Swann, and Pickett 2005). Consistently, a positive correlation is identified between the quality of facilitation, student satisfaction, and student perceptions of learning. These findings and the reflective suggestions of dozens of distance educators suggest strongly that skilled and energetic moderators play an important role in facilitating critical discourse and collaborative meaning making.

For various reasons (some more defensible than others), the role is not always taken up successfully. This gives rise to an alternative means of addressing the essential roles and responsibilities. Sophisticated conferencing systems, referred to as computer support for collaborative learning (CSCL) systems, provide technological proxies for responsible facilitation. Duffy, Dueber, and Hawley (1998) developed a conferencing system that compels students to participate in a circumscribed manner. In place of the generic options for posting a message offered by most conferencing systems (e.g., post, reply), their system offers options such as rebut, add evidence, and challenge assumption. Jonassen and Kwon (2001) have studied the use of a similar system. The system, which they refer to as a "computer-supported collaborative argumentation system" (CSCA), is designed to scaffold argumentation among students. It offers the following conversational ontology: hypothesis, data, and principles, along with for and against. When using this system, Jonassen and Kwon found that students were able to construct coherent arguments more often than students using a conventional conferencing system. They analyzed students' interactions using Toulmin's (1958) familiar system of informal argumentation and found significantly more evidence of claims, grounds, and rebuttals among the CSCA group. Knowledge Forum™ is probably the most widely known effort to guide student interaction into a particular conversational genre. Scardemalia and Bereiter's (1994) CSCA delimits student interaction to patterns that are characteristic in scientific research communities, including: my theory, I need to

understand, new information, this theory cannot explain, a better theory, and putting our knowledge together. Dozens of studies demonstrate the efficacy of this product in the K-12 settings for which it was designed (e.g., Scardemalia and Bereiter 1994), and similar work has begun in postsecondary settings (van Aalst and Chan 2002).

Discussion facilitation, through either skilled and energetic instructors or technological proxies, is one means of addressing the lack of critical discourse or collaborative meaning making in computer conferencing. The final suggestion we explore is implementation of appropriate learning activities.

Looking closely at the types of learning activities that underlie reports of computer conferencing, Rourke and Conrad (2004) found two common designs. In the most prevalent, students engage in week-long, whole-group, open-ended forums. Consistently, this design is associated with low levels of participation and interaction and few instances of critical discourse or collaborative meaning making. In the second design, a whole class is divided into small groups of students who engage in purposive collaboration (e.g., case-based learning, problem-based learning). This design is associated consistently with high levels of participation, participation that is predominantly interactive, and many instances of knowledge co-construction. Villalba and Romiszowski (2000), Kanuka (2005), and Kanuka, Rourke, and Laflamme (2006) report similar findings. Villalba and Romiszowski, for example, performed a comparative analysis of online courses and found that few emphasize collaborative, small-group learning. Most offered a relatively unstructured online group discussion. Assessing these courses, the authors conclude:

There is little if any research indicating that such environments are conducive to in-depth reflective discussions of the type required to develop critical and creative thinking skills. And there are some studies that suggest they are singularly ineffective in this respect. (p. 405)

Pena-Shaff and Nicholls' (2004) research sheds light on why small-group purposive collaboration can be more valuable than open-ended, whole-group forums:

In the open forums, if one student disagreed with another, she/he could simply ignore the comment. The small group activity, however, required the students to reach some degree of consensus about their project. If they disagreed with someone, or felt someone else's argument was not well developed, it was more important for them to challenge or contradict them to ensure the presentation would be coherent. (p. 64)

Together, the results of Kanuka, 2005; Kanuka, Rourke, and Laflamme (2006), Pena-Shaff (2000), Rourke and Conrad (2004), and Villalba and Romiszowski (2000) remind distance educators of a conclusion that is well established throughout the literature: Instructional methods have a greater effect on teaching and learning than instructional media (Clark 1994). Hopefully, our review has reminded readers that computer conferencing, in and of itself, is not a pedagogy. Our developmental

review indicates that it has taken over twenty years for teachers, students, and researchers to fashion a role for computer conferencing in distance learning.

CONCLUSION

Computer conferencing was invented in the early 1970s (Hiltz and Turoff 1993) and made its way into distance learning in the mid-1980s (Harasim 1990). The union represented the intersection of two growing movements that we remain in the midst of: (1) the maturation of networked computing as a stable and diffuse technology, and (2) a growing recognition of the importance of interaction for learning. The asynchronous mode of communication presented by computer conferencing provides distance learners with a means of interaction while preserving the "anywhere anytime" quality that draws many students to this type of formal education. Since its introduction thirty years ago, there have been many advances in computer networks, communication software, and learning theories; yet computer conferencing continues to expand its role in many levels and types of education.

Therefore, it is important for us to conclude by revisiting some of the problems that persist across the models we reviewed and to see how they are being addressed. The problem, generally, is the students' reluctance to use this technology to engage in either critical discourse or collaborative meaning making—two sets of conversational activities that provide the rationale for including computer conferencing in a course. Documented solutions to this general problem, which we sketch below, include: (1) skilled and energetic facilitation of online discussions, (2) sophisticated conferencing systems that assume some of the roles and responsibilities of successful facilitators, and (3) learning activities that encourage critical discourse and collaborative meaning making.

We conclude that the prescribed processes and outcomes—that is, critical discourse and collaborative meaning making, are unlikely to materialize in the absence of (1) skilled and energetic facilitation, (2) sophisticated conferencing systems that assume some of the responsibilities of successful facilitators, or (3) learning activities that encourage productive and meaningful communication.

GLOSSARY

Andragogy: With the rise of social phenomena such as lifelong learning, educational theorists began to make categorical distinctions between teaching and learning with children, referred to as *pedagogy*, and teaching and learning among adults, referred to in some quarters as *andragogy*.

Asynchronous Communication, Textual: In the context of educational computer conferencing, *textual* refers to message production that is limited to the characters on a computer keyboard; *asynchronous* refers to communication is somewhat liberated from the temporal and orchestral constraints of face-to-face communication.

Computer-Assisted Instruction: For many, the adoption of computer conferencing signaled a shift in the

way computers were used in distance learning. In contrast to this communicative function, they had previously been used in a limited way to present structured, preprogrammed learning materials. This was referred to as *computer-assisted instruction*, and is easily distinguishable from *computer-mediated communication*.

Correspondence Education: Sometimes referred to as *first-generation distance education*, correspondence education involved courses of study in which students and teachers communicated by mail.

Critical Discourse: A particular pattern of interaction in computer conferencing that advocates associate with favorable learning outcomes. In Wegerif's description, it involves interaction in which partners engage critically but constructively with each other's ideas. Relevant information is offered for joint consideration. Proposals may be challenged and counterchallenged, but if so, reasons are given and alternatives are offered. Agreement is sought on a basis for joint progress. Knowledge is made publicly accountable and reasoning is visible in the talk.

Distance Learning: In Keegan's definitive conceptualization, distance learning is a form of education characterized by: (a) the quasi-permanent separation of teacher and learner throughout the length of the learning process, (b) the influence of an educational organization, (c) the use of technical media, (d) the provision of two-way communication, and (e) the quasi-permanent absence of the learning group throughout the length of the learning process.

Technological Characteristics Perspective: A variant of technological determinism specific to the study of communication technologies. Stated briefly, attributes of media exercise a predictable causal influence on users' actions. One of the central projects of this perspective was to rationally and efficiently match the properties of a medium to the characteristics of a communication task.

Technological Determinism: The notion that user behavior is determined by particular features of a technology, which in turn is regarded as an autonomous agent outside the influence of human beings.

Tutors: Content specialists (but not necessarily at the level of subject-matter experts in the course design team) who provide instructional guidance to students during a distance education course. Tutors typically provide feedback to students on their assignments, but are not involved in the course design.

INTRODUCTION

The term *electronic commerce* came into widespread usage after the first graphical Web browser—Mosaic—was developed in 1993 and freely distributed around the world. Drawn by the ease of use of the browser, millions of home consumers, businesses, and educators connected to the Internet, creating the conditions for Internet-based commerce. Indeed, Nielsen/Netratings estimates that there are nearly half a billion people worldwide who have access to the Internet from home as of December 2006 (this number rises if we also include those who access the Internet from work or other public settings; see www.nielsen-netratings.com for the latest monthly estimates). Businesses, often backed by venture capital from investors enamored with the new opportunities created by Internet-based business, flocked to the Internet, attracted by the ease of setting up electronic storefronts and the potential access to a global market of Internet subscribers. For example, Laudon and Traver (2003) estimate that more \$120 billion was invested in 12,450 Internet start-up companies between 1998 and 2000, a period of significant growth in e-commerce. Impressively, despite the highly publicized dot-com failures in 2000 and 2001, Internet sales of goods and services to consumers (i.e., business-to-consumer, or B2C, e-commerce) have grown steadily, exceeding \$88 billion in 2005 and expected to easily surpass \$100 billion in 2006 in the United States (U.S. Department of Commerce 2007). Growth in other parts of the world, and especially Europe, is equally impressive. Forrester (www.forrester.com) estimates that 2006 online sales in Europe exceeded €100 billion with a growth rate that is even higher than that in the United States. Even more dramatic has been the extent to which businesses have adopted e-commerce to support exchanges with other firms, such as suppliers and business customers, referred to as business-to-business

(B2B) trade. The U. S. Department of Commerce (2006) has reported that e-commerce shipments accounted for over 21 percent of the total value of manufacturing shipments, or \$843 billion in 2003, while nearly 17 percent, or \$730 billion, of all merchant wholesaler sales were accomplished via e-commerce in the United States in 2003. In Europe, across twenty industry sectors, 48 percent of firms report placing orders for supplies online (e-Business Watch 2006).

Chapter Overview and Themes

This chapter examines the ongoing development of e-commerce and its influences on the way that companies work with their suppliers and market their products to customers. The next section begins with a look at the historical development of e-commerce, which suggests that it emerged as a powerful force only once a truly open and standard data network—the Internet—was coupled with easy-to-use software—the graphical Web browser. The section on e-commerce development continues by noting that despite the dot-com bust in 2000 and 2001, e-commerce usage has increased steadily, and affects a growing proportion of economic activity in the industrialized world. The next section explores aspects of the basic technological infrastructure that supports e-commerce, focusing on the increasing emphasis on the role of standards, especially for B2B transactions, evolving methods in the ongoing battle against security threats, the explosion in both broadband and wireless access, and the rapid emergence of a range of new approaches to e-commerce models and designs, often termed Web 2.0. Then we explore e-commerce from a business opportunity perspective, noting that thousands of Internet-based companies have flocked to capitalize on this new platform, equipped with innovative, albeit

at times not all that effective, business models. Then we take a closer look at approaches to online retailing, focusing on the increasingly clever marketing strategies used by e-commerce companies. The next section provides a brief look at B2B e-commerce, exploring the role of this evolving exchange medium in the supply chain. We go on to examine one area in particular in which e-commerce has had an enormous impact—the content industries—in which new models for the sale of online content have challenged traditional print, music, and video publishing. Next is a brief review of research on a number of anticipated impacts of e-commerce, highlighting the need to critically assess the early hype about the effect of e-commerce on market structures, prices of goods and services, and problems of trust in the relationships between an online business and its stakeholders. The chapter concludes by summarizing key themes and issues for further research.

DEFINITION, HISTORY, AND CURRENT STATUS

What Is E-Commerce?

Today the term *electronic commerce* (or *e-commerce*) most commonly refers to the process of buying and selling goods—both information and tangible products—and services over the Internet. Earlier definitions (e.g., Clarke 1999) emphasized the “conduct of commerce in goods and services using telecommunications-based tools.” More recent definitions (e.g., Laudon and Traver 2003, 10) emphasize the “use of the Internet and the Web to transact business” in what they call “digitally enabled commercial transactions,” in which there is some “exchange of value across organizational or individual boundaries in return for products and services.” Narrower definitions require that complete transactions, including ordering and payment, occur entirely via the Internet, while broader definitions include information exchange in support of transactions, even if the actual payment occurs outside the Internet (often called “offline” payment). Intermediate approaches, such as the one used by the U.S. Department of Commerce, require that an order occur online, although payment may still be made offline.

The term *e-business* is also used frequently, which refers more broadly to the conduct of business over computer networks. E-business includes activities that are not purely commercial transactions, such as when two firms use the Internet to collaborate on product development or research, or a firm provides customer service online. Some (e.g., Laudon and Traver 2003) consider e-business to include only internal applications of a firm’s computer network, and not transactions that span to other firms. Here we will consider *e-business* to be a broader term, referring to a range of intraorganizational and interorganizational interactions over computer networks, including but not limited to e-commerce. *E-commerce*, then, refers to the process of buying and selling goods and services over a computer network.

In most e-commerce research and discussion, business-to-consumer (B2C) transactions are considered as a distinct topic from business-to-business (B2B) exchange.

There are good reasons for this, as B2C exchanges are often ephemeral retail transactions that are typically smaller in value, and involve customers with whom there is little to no long-term relationship. B2B exchanges are typically larger in value, are structured by contracts, and are often shaped by existing relations between buyer and seller. Although some B2B exchanges resemble retail trade, on the whole, it makes good sense to study the kinds of buyer-supplier and buyer-distributor electronic exchanges through a different lens than one would study online shopping by consumers.

History of E-Commerce

Long before the World Wide Web, electronic networks were used to support transactions between businesses and their various external constituents (e.g., suppliers or customers). In the 1970s, forward-thinking manufacturers and wholesalers deployed proprietary data networks and simple terminal-based remote ordering systems to the premises of business customers. The value of computer networks to link business buyers and sellers was soon well established, and efforts to create standard electronic documents to support trade were occurring across many industries. These latter standards were collectively called EDI (electronic document interchange). In some industries, such as automobile manufacturing and chemical production, EDI transactions proliferated because large dominant manufacturers mandated their use. However, because EDI standards were complex and costly to implement, especially for small businesses, the extent of its diffusion was limited (Markus et al. 2006).

There were precursors to consumer-based e-commerce as well. The Home Shopping Network on cable television and the many 1980s-era electronic information services collectively known as videotex in Europe and the United States resembled Web-based electronic retailing. The most successful of these systems in Europe was the French system popularly known as Minitel, named after the small terminal that initially was freely distributed to telephone subscribers. Beginning in 1983, French telephone subscribers could use their Minitels to look up a wealth of information, engage in home banking, and order a wide range of goods and services, such as tickets, groceries, and other consumer products. Like the Internet, these services were offered over a public network to which anyone could connect, used a single standard, and relied extensively on graphical content. Unlike the Internet, a clear payment model was implemented, with France Telecom (at the time, the public administration responsible for the provision of all telecommunications networks and services in France) providing a “billing and collection” service for all companies that wished to sell via the Minitel. Consumers received the bill for their Minitel use on their regular phone bill, and France Telecom in turn paid the various service providers (Steinfeld, Kraut, and Plummer 1995).

In contrast, American electronic information services of the 1980s were still based on closed, rather than open systems, using what has been called a “walled garden” approach. That is, services like CompuServe and America Online (which are now merged) used their own proprietary networks, and their content and services

were available only to their subscribers. It was not until commercial traffic was permitted on the Internet that consumer-oriented e-commerce as we know it today was born.

The early years of e-commerce had all the characteristics of a gold rush, as companies flocked to the Web to set up their electronic storefronts. Lured by the rapid growth of first movers like Amazon.com, more than \$125 billion in investment capital was poured into Internet initial public offerings (IPOs) between 1996 and 2000 (Laudon and Traver 2003). The birth of a new digital economy was proclaimed, characterized by seemingly unending growth in productivity rooted in the supposedly frictionless commerce afforded by the Internet. The new Web-based businesses theoretically offered benefits such as access to a larger potential market, lower inventory and building costs, more flexibility in sourcing inputs, improved transaction automation and data mining capabilities, an ability to bypass intermediaries that added costs but little value, lower costs for adjusting prices (known as a menu costs), enabling more rapid response to market changes, increased ease of bundling complementary products, 24/7 access, and no limitation on depth of information provided to potential customers (Steinfeld, Mahler, and Bauer 1999). With all these advantages, and the reduced search costs faced by consumers, prices were expected to be lower, and Internet firms would prosper.

Despite the rosy projections for e-commerce, in late 2000 and early 2001 many of the dot-com companies began to fail. Few ever made any profits, as their business approach revolved around scaling up to increase market share (Hawkins 2004). This approach was based on the belief that Internet businesses would enjoy positive network externalities—implying that the more people who used a site, the more value it would have for each user. The dot-coms that could rapidly attract the largest number of users would thus have an insurmountable competitive edge. In search of the required scale, Internet firms kept prices too low and quickly burned through the cash raised from venture capitalists. At the same time, the U.S. economy began to slip into a recession, and venture capitalists began to lose faith in the viability of start-ups that failed to return any profits. Stock

prices, which were far too high by normal investment standards, dropped precipitously, and the venture capital community lost interest in dot-com businesses. By the end of 2001, the dot-com era was over, and by one estimate only about 10 percent of the dot-coms created since 1995 still survived (Laudon and Traver 2003).

B2B-oriented dot-coms experienced much the same fate. Large numbers of B2B electronic marketplaces were created to help match buyers and sellers in many industries, and by early 2000, more than 750 B2B e-markets were operating worldwide (U.S. Department of Commerce 2000). Yet most of the new dot-coms in this arena failed as well.

Current Status

Despite the problems of the dot-coms, statistics on e-commerce use do show steady gains, particularly as traditional companies have moved to enhance their offerings with Internet-based sales channels. According to U.S. Census figures, even as the dot-coms were failing and the economy went through a recession, retail e-commerce sales in the United States grew at a brisk pace (see Figure 1). Annual U.S. retail e-commerce sales have more than tripled between 2000, the first full year that the government tracked this statistic, and 2005, rising from approximately \$27.8 billion to more than \$88 billion (U.S. Department of Commerce 2007), and today is estimated to account for approximately 3 percent of all retail sales. In the all important fourth quarter, during which holiday shopping occurs, online sales exceeded \$27 billion in 2005, more than five times the total in the fourth quarter of 1999. Even more telling is the fact that online sales growth is far higher than the rate of growth in traditional retail formats, averaging more than 28 percent for the same quarter across years compared to just 4.6 percent for total retail sales. These census figures are a low estimate, since they do not include sales from online travel, financial brokers, and online ticket sales.

U.S. B2B online trade dwarfs B2C e-commerce, accounting for over 94 percent of all e-commerce activity, according to Commerce Department statistics. It has also grown more rapidly than offline trade. Manufacturing

Figure 1: Quarterly U.S. Retail E-commerce Sales, Fourth Quarter 1999 to Third Quarter 2006 (Source: U.S. Department of Commerce 2007)

online sales, for example, grew at a greater than 12 percent rate from 2002 to 2003, while offline sales grew only 1.5 percent (U.S. Department of Commerce 2006).

Global Trends

The United States was an early adopter of Internet-based commerce, but now this commerce is growing rapidly in other parts of the world. As noted earlier, Forrester estimates that European retail e-commerce to total more than €100 billion for 2006. The OECD (2006, *Measuring the information economy*) provides estimates illustrating how e-commerce use varies considerably across countries (Figure 2). Outside the United States, e-commerce use in 2005 was heaviest in Northern Europe, Canada, the advanced Asian economies, and Australia and New Zealand. Southern and Eastern European countries, less developed regions of Asia, Central and South American countries, and African countries have lagged beyond, largely because of the lack of the requisite infrastructure to support e-commerce. Analyses of global e-commerce trends point to differences in policies toward the Internet and broadband deployment; cultural differences in terms of shopping preferences, use of credit cards, and perceptions of privacy; and other geographical and economic factors to explain these differences (Kraemer, Dedrick, and Melville, 2006).

Increasingly, e-commerce is being seen as a crucial benchmark for determining the strength of national economies. Since 2001, for example, the World Economic Forum has published an annual Global Information Technology Report in order to track the progress that countries have made in using ICT to enhance productivity in business. The 2005–2006 report includes a “networked readiness index” to compare the world’s economies on how well they incorporate use of the Internet and other ICT by businesses, governments, and individual consumers. Their most recent report reveals the startling progress in

some of the formerly least developed countries with regard to online commerce, especially India, while noting that the most competitive countries remain the traditionally strong Internet using nations such as the United States, Singapore, and the Nordic countries in Europe (Dutta, Lopez-Claros, and Mia 2006). The OECD devotes an entire chapter in the 2006 Information Technology Outlook to the dramatic growth of the Internet and e-commerce in China, although most of the growth is in the eastern coastal cities (OECD 2006, *Information Technology Outlook 2006*). In Europe, policy makers have established the e-Business Watch, an annual assessment of the ever-growing penetration of ICT-enabled business within the European context. Their detailed annual surveys reveal the spread of e-commerce for both B2C and B2B trade in twenty industries (e-Business Watch 2006). Nearly half (48 percent) of all firms order supplies online, and 25 percent now accept orders from customers online. Since larger firms are more likely to use e-commerce, these numbers increase to 57 percent and 35 percent when evaluated by percent of employees rather than percent of firms. Clearly, e-commerce is a global phenomenon, but requires strong national policies favoring the deployment of the underlying telecommunications infrastructure, a financial infrastructure, and a cultural environment that is compatible.

THE CHANGING NATURE OF E-COMMERCE INFRASTRUCTURE, TECHNOLOGY, AND TECHNIQUE

The infrastructure to support e-commerce is constantly evolving, and includes the underlying wired and wireless networks that carry traffic as well as the devices that connect to these networks; the protocols, software, and scripting languages that define how information is carried and how e-commerce applications are built,

Figure 2: Percent of business with more than 10 persons using the Internet for selling and purchasing in selected countries in 2005 (No data were available for Internet business purchasing in Japan; data for New Zealand are from 2001, from Switzerland 2002, from Iceland and Mexico 2003, and from Australia 2004–2005.) (Source: OECD 2006, *Measuring the information economy*)

including a focus on standards to enable interoperability across e-commerce applications built by individual firms; technical approaches to providing a secure and private environment within which transactions can be made; and changing business and interface logics enabled by these technical developments. A brief introduction to some of the evolving topics in this area follows.

Broadband Wired and Wireless Networks and E-Commerce

The technologies that support e-commerce are constantly evolving, creating new capabilities and opportunities. Although space does not permit a review of all of the many technological developments that are shaping the future of e-commerce, the continued development of both wired and wireless access networks has strong implications because of their effect on improving customer experiences and spreading access to mobile customers.

The Internet-using population across the world is continuing to transition from slower dial-up lines to broadband access using DSL (digital subscriber line) and cable modem technology providing at least 256 kbps (OECD 2006, Telecommunications and Internet policy). Across the 30 OECD countries, the number of broadband subscribers went from 13.6 per 100 inhabitants in December 2005 to 15.5 in June of 2006, with some countries, like Denmark and the Netherlands, having a broadband subscriber population of nearly 30 of every 100 people (see Figure 3). Since households typically have more than one person, the actual proportion of the population with direct broadband access is quite high.

In the United States, broadband penetration is high, with more than two-thirds of active Internet users subscribing, according to statistics released by Nielsen/Netratings through February 2006.

In addition to wireline access, there has been tremendous innovation in the area of wireless network infrastructure, improving the bandwidth of connections as well as capabilities of handheld and portable devices. Next-generation cellular networks (often termed 3G, or third generation) have been deployed across the world, and broadband connections are increasingly available. Moreover, wireless local area networks (LANs) based on the Wireless Fidelity (Wi-Fi) (i.e., IEEE 802.11) family of standards are widely deployed with a range of subscription and ad hoc access from many public venues. Cellular and Wi-Fi wireless infrastructures are complemented by newer WiMax (IEEE 802.16) standards that provide broadband access over wider areas where the economics make sense (e.g., rural areas not currently served by 3G cellular, DSL, or cable broadband networks). Mobile handset manufacturers are increasingly building handsets with enhanced data capabilities, including some mobiles that switch between cellular and Wi-Fi, as well as other wireless standards for nearer-field connections such as Bluetooth. As next-generation cellular infrastructures speed up access times, people will no longer be tied to a desktop computer in order to surf the Internet and shop online. They are free to engage in e-commerce anytime and anywhere.

How will e-commerce be impacted by these new mobile capabilities? Surprisingly, even before Web-enabled phones have achieved widespread adoption, early forms of mobile commerce have occurred with simple text messaging (e.g., via short message service, or SMS). Cell phone users simply made purchase requests or responded to advertisements by sending SMS messages to special numbers. Today, broadband wireless is mainly impacting the sale of content, through the downloading of ringtones, music, video, and information. New approaches that better integrate other forms of

Figure 3: Broadband Subscribers in OECD Countries per 100 Inhabitants: December 2005 and June 2006 (Source: OECD 2006, Telecommunications and Internet policy)

e-commerce with mobile devices are appearing, for example, in areas such as mobile payment and location-based services. Indeed, many mobile e-commerce (or m-commerce) services will be based on the particular location of shoppers, allowing someone in a car, for example, to find the nearest vendor of a particular product (Steinfeld 2004). In the United States, the Federal Communications Commission (FCC) has mandated that all cellular operators be capable of determining the location of cell phone users in order to support emergency 911 services. However, numerous e-commerce uses of location data, and a wide range of services, beginning first with navigation support, are now, or will soon be available. Users may use their mobile device to search for available vendors in an area, receive directions from their current location to a vendor, make payments at the point of sale, and receive advertisements based on their interests when they near particular locations. Location-based services thus blend e-commerce and physical commerce in new ways, blurring the traditional online/offline distinctions of the past.

The integration of wireless devices into e-commerce is extending beyond mobile phones, leading to innovative applications for tracking inventory and product usage. Radio-frequency identification (RFID) tags, for example, can enhance supply-chain performance, and are being adopted by some of the world's largest retailers, albeit with some concerns about market power and intrusiveness (McGinty 2004). Tags may be embedded in products, so that information can be transmitted from a customer to a reader in many different locations. An RFID tag on prescription drugs in an Internet-enabled cabinet might trigger an automatic reorder from a pharmacy after a specific date has passed, for example.

The Internet and E-Commerce Standards

E-commerce use exploded in 1994, built on an open, standard computer network—the Internet. The mandated use of the TCP/IP standard ensured data connectivity while markup standards such as hypertext markup language (HTML) ensured some degree of consistency in the presentation of information. Continuing development of markup languages, and in particular, languages that deal with semantic issues in addition to presentation, has altered the e-commerce landscape. Extensible markup language (XML) has had a significant impact on e-commerce, especially between businesses, helping to move it from a basic presentation focus to a transactional focus. Like HTML, XML relies on tags to mark up text files. However, the emphasis is not on tags that define how information is to be formatted and presented, but on tags to describe data (see Dorfman [2004], for a detailed description of how XML works). Moreover, users can define their own tags (hence, the notion of “extensible”) based on the data they are providing. XML makes databases portable over the Internet, and has been the basis for a growing family of transaction standards. As more firms use XML-based standards, particularly for B2B transactions, a new opportunity has arisen to develop industry-wide data standards. Essentially, XML has become an enabler for EDI over the Internet. Markus and colleagues (2006), have documented the growth of vertical industry

standards using XML, illustrating the many challenges that industries face in agreeing on such factors as data definitions, transaction formats, and the like.

Building on XML, another e-commerce infrastructure development to highlight here is the growth in Web services. Web services are self-contained, modular e-commerce applications built on standardized protocols, made available over the Internet to e-commerce users and vendors through standardized XML messaging (Ritsko and Davis 2002). For example, a shopping cart function is a common Web service that a merchant may use to support its e-commerce site, rather than writing its own cart software. In order to enable Web services, standards for making XML-based requests (simple object access protocol [SOAP]), describing the services that are available (Web services description language [WSDL]), and publishing service descriptions in online directories in a manner that permits requesters to search for needed services (universal description, discovery, and integration [UDDI]) are required (Gottshalk et al. 2002). Some of the most famous Web vendors now enable business partners to link to their service via a Web services architecture (e.g., see Amazon.com's Web services offerings at www.amazon.com). As the notion of Web services continues to expand, so too do efforts by major software vendors to provide development platforms to speed up service deployment. Microsoft's .NET platform and Sun's J2EE are the two most well known today (Sahai, Graupner, and Kim 2004).

Encryption Methods in E-Commerce

Another fundamental part of the e-commerce infrastructure is the set of technologies aimed at ensuring the security of online transactions. Lack of trust in an online store, fear of financial loss through theft of a credit card or other banking information, and other concerns over the privacy of information transmitted to and stored by an online store are just some of the concerns faced by consumers in e-commerce transactions. In the earliest years of e-commerce, fears that credit-card information would be intercepted while in transit over the Internet prompted most online stores to implement secure servers relying on secure sockets layer (SSL) transmission. However, e-commerce security involves much more than secure transmissions. Among the many requirements are needs to authenticate both consumers and online stores, preserve the confidentiality of information related to online transactions, and ensure the integrity of transaction-related information. Public and symmetric key encryption systems are two fundamental techniques for accomplishing these needs, which then must be incorporated into a broader public key infrastructure (Juels 2004). In a symmetric key system, the same code is used to encrypt a message (i.e., the credit-card number or the order for a product) as to decrypt it. Hence, the sender and receiver must both possess the secret key needed to decode the encrypted text (also called ciphertext, as opposed to a plaintext message). The main problem with symmetric key approaches is that it is difficult to distribute the secret key safely. In public key encryption systems, a pair of codes is needed to encrypt a plaintext message into

ciphertext and then decrypt it to plaintext again. A person or a store is assigned both a public key that is published and available to anyone (often called a “certificate”), and the matching private key that only its holder possesses. In this way, public key encryption systems are able to accomplish the needs for authentication and confidentiality noted above, without suffering from the problem of how to send secret keys over the insecure Internet. To ensure confidentiality, buyers use an online store’s public key to encrypt the message. Then, only the store would possess the matching private key, ensuring that only it would be able to decrypt the order. Buyers using their private key authenticate themselves, since only their public key decrypts the order. In practice, public key encryption is processing-intensive, and is therefore impractical for large transmissions. The solution is to use a combination of systems, with symmetric keys used for much of the encryption, but public keys used to encrypt the symmetric keys for transmission.

Public Key Infrastructure

To enable fuller use of public key encryption systems in practice requires a trusted system to assign the keys in the first place, and make sure that only the rightful owners obtain them. In addition, keys may need to be revoked in the event they are abused or appropriated by the wrong entities. Such a trusted party is often called a “certificate authority,” and the system to accomplish this is called a “public key infrastructure” (PKI) (Housley and Polk 2001).

Encryption technology is evolving to help establish a more secure line of communication between online vendors and their buyers. However, some of the most-well-known breaches of security have occurred outside the buyer-seller transaction link. In particular, one critical issue is the need to secure buyer information, such as a credit-card number, once the vendor receives it. Servers storing thousands of credit-card numbers are more desirable targets for hackers than an individual transaction. In fact, one of the most widely publicized e-commerce security breaches to date occurred when a hacker compromised CD Universe’s database, reportedly stealing 350,000 credit-card numbers (Wolverton 2000). The hacker attempted to extort \$100,000 from CD Universe, and when that failed, posted thousands of stolen card numbers on a public Web site. This illustrates that e-commerce security encompasses more than secure transactions, and must include a broad range of security practices that protect customers’ information even after purchases take place.

Changing Interface and Business Logics: Web 2.0

Web 2.0 is a broad collection of ideas, techniques, and applications with a label derived from an influential conference about the emergence of the Web as a platform for businesses and services (O’Reilly 2005). Among the themes, some of which have already been mentioned in this chapter are:

- Richer, more interactive interfaces on the Web. For example, site developers have increased their use of

programming strategies like Asynchronous Javascript and XML (AJAX) that allows animation and new content to appear without the tedious process of a new page load. The Gap, for example, recently re-engineered their entire e-commerce site (www.gap.com) to take advantage of this technique, allowing customers to view product details without ever leaving the product category page.

- Leveraging the long tail. *Long tail* refers to the traditional “power law” distribution that has been used to describe the popularity or frequency of occurrence of things like Web-site page views (Adamic and Huberman 2001). A small number of pages are viewed by a large number of Internet users, for example, while a very large number of pages are viewed by a very small number of people. For merchants, this can mean that a small number of products will be popular with large numbers of shoppers, while many products are desired by only a few people. In a traditional store, inventory costs militate against holding these less-popular products, but on the Internet, they can be offered without holding them in inventory. Industry observers now argue that e-commerce will reshape business inventory practices, as merchants benefit from the increased sales by offering more than the blockbuster hits, and aggregating across the many items in the long tail (Anderson 2006).
- Capitalizing on user co-production and harnessing collective intelligence. Users can increase the value of an e-commerce business by contributing their own content such as product usage know-how that enhances any business’s offerings. E-commerce businesses are increasingly adding community tools to their sites for this purpose.
- Using interfaces that enable syndication and “mash-ups.” Syndication tools like RSS (meaning either “rich site summary” or “really simple syndication”) enable sites to keep users up to date without requiring them to check in regularly. Mash-ups allow a site to create new services by combining its content (e.g., maps) with another site’s content (e.g. houses for sale that can then be located on a map, such as HousingMaps.com that represents a mash-up between Craigslist and Google Maps). Tagging of content such as photos and videos allows it to be searched and more easily incorporated into other sites (e.g., users’ photos from a photo-sharing site like Flickr might be brought into a news site to enhance coverage).

E-COMMERCE BUSINESS MODELS

Many innovative methods of doing business were created in the early years of e-commerce, which collectively came to be called “Internet business models.” Exactly what constituted a business model was the subject of much debate, as was the issue of which models were successful. Rappa (2004), for example, defines a business model as the “method of doing business by which a company can sustain itself—that is, generate revenue. The business model spells out how a company makes money by specifying where it is

positioned in the value chain.” Timmers (1998) considers a business model to include three basic components: (1) the architecture for the product, services, and information flows, (2) the potential benefits for the various business actors, and (3) the sources of revenues. Weill and Vitale (2001) characterize models as the roles and relationships among a firm’s major stakeholders that result in flows of products, information, and money, leading to benefits for the participants. Other scholars offer what might be called an *ingredients* perspective on Internet business models, suggesting that they each contain many facets, such as: a value proposition, sources of revenue, a market opportunity, a competitive landscape, a competitive advantage, a strategy for promotion in the market, an organizational

development plan, and a management team (Afuah and Tucci 2001; Laudon and Traver 2003).

Along with the numerous definitions of business models can be found many taxonomies of models that are commonly seen on the Internet. Three well-known taxonomies are summarized in Table 1. Although direct comparisons of models are difficult, given the varying perspectives the authors have used in forming categories (Wang and Chan 2003), these models do illustrate the range of approaches stimulated by e-commerce capabilities, ranging from simple translations of offline retail practices to complex match-making services in brokerage configurations to emerging community-based models supported by users and/or advertising.

Table 1: Taxonomies of Internet Business Models

Author(s)	Internet Business Models	Comments
Timmers (1998)	E-Shop E-Auction E-Mall Third-Party Marketplace E-Procurement Virtual Communities Value-Chain Integrators Collaboration Platforms Value-Chain Service Provider Information Brokerage Trust Services	In this early typology, Timmers organized observed models along two dimensions: (1) the degree of innovation (i.e., difference from traditional business models), and (2) the degree of functional integration. E-shops are simple translations from offline models, with low innovation and low integration of functions. Third-party marketplaces provide a number of functions for both buyers and sellers, and are seen as relatively more innovative.
Rappa (2004)	Brokerage Advertising Infomediaries Merchant Manufacturer Affiliate Community Subscription Utility	These models are largely organized by the primary source of revenue. For example, brokerage models such as eBay rely on fees or commissions. Infomediaries give discounted or free goods or services, while they collect consumer information and sell to marketers. Affiliates derive revenue by referring customers to other e-commerce firms, who then provide a sales commission. Utility models refer to firms that charge customers on a metered, or pay-per-use basis. In some cases, the models refer to a primary way in which value for customers is created—e.g. community models rely on users with common interests to provide content, so that they can charge for advertising. Also, within each model, Rappa defines many subtypes, such as the click and mortar vs. virtual merchant business models in the merchant category.
Laudon and Traver 2003	B2C Portal E-Tailer Content Provider Transaction Broker Market Creator Service Provider Community Provider B2B E-Distributor E-Procurement Exchange Industry Consortia Private Industrial Networks	These authors divide models by their consumer vs. business focus. Within model types they describe the value proposition, as well as the many subtypes. For example, portals offer an integrated package of content and services, and can be horizontal (targeting all users) or vertical (focused on a specific subject matter or market segment). Moreover, they illustrate that many Internet business models combine a number of sources of revenue, including advertising, subscription fees, transaction fees, margins on sales, and affiliate fees. In the B2B arena, they further illustrate the importance of private networks and industry consortia—models that suggest that existing business relationships are essential, even for Internet-based transactions.

After the dot-com crash, attempts to list the many observed Internet business models gave way to analyses focusing on what was wrong with the models. For example, early in the e-commerce boom years, many felt that revenue from advertising would sustain e-commerce. This made some sense for content firms, such as online newspapers, magazines, radio stations, and other media-oriented companies that were accustomed to reliance on sponsors to bring down the costs for their viewers, listeners, and readers. However, one failed Internet business model, pursued somewhat by Buy.com, involved the use of advertising revenue to subsidize product sales, so that consumers could buy products at heavily discounted prices. Another problematic business model in the B2C arena involved manufacturers of products selling directly to end consumers and bypassing wholesale and traditional retail channels. Levis, for example, attempted to sell its blue jeans directly to online shoppers. Existing retailers, however, threatened retaliation. Given the relatively small percentage of sales generated by the Internet, Levis soon gave up on the direct-sale model and now uses its Web site mainly to promote sales of Levis at traditional retail outlets or to sell online through its retailers' Web sites.

Hawkins (2004) criticizes the notion that the Internet required altogether new business models, arguing instead that it simply enabled some firms to apply models that heretofore had not been used by them in their particular market, but that had been common in markets for other types of goods and services. Moreover, he argued that a model does not convey competitive advantage in and of itself, but only if there were reasons to expect that a firm could prevent others from easily imitating it.

Critics of the early business model literature also point out that the dominant focus on revenue streams can encourage firms to ignore other benefits that e-commerce offers, such as cost reductions, improved customer relations, or enhanced performance of traditional channels (Steinfeld, Bouwman, and Adelaar 2002). For example, a virtual merchant may be able to offer goods at lower prices because of its lower inventory holding costs and lower selling costs. On the other hand, a click-and-brick firm may use its Web site to help generate more traffic in its physical stores by offering coupons or searches of in-store inventory (Steinfeld 2005).

Despite the critiques, it is clear that the development of online commerce has enabled the application of many innovative strategies. One way to view the dot-com crash was simply as an inevitable shakeout that always follows the rapid entry of firms into a new area of business. In this perspective, the models that survived represent the winning approaches, promising significant opportunity for the firms that have successfully adopted them.

ONLINE RETAIL MARKETING STRATEGIES

E-commerce gives merchants many opportunities to enhance the way products are marketed to customers, stemming from the information capture and manipulation capabilities of computer-mediated commerce, as well

as the networking and community-enabling affordances of the online world. These affordances make it possible to personalize and customize interactions with consumers in much more sophisticated ways than heretofore possible, at least by larger retailers. They provide better tools to match products and product features with consumer preferences, and enable joint efforts among vendors of complementary products to meet demand. Through creative application of data on past purchases, buyer loyalty and incentive programs can increase switching costs and lock-in. Moreover, by connecting with customers in new ways, through multiple channels including customer to customer interactions, e-commerce can capitalize on multichannel and viral marketing opportunities and give buyers access to a wealth of untapped knowledge.

Personalization, Customization, and Recommendation Systems

By supplying information about preferences, as well as information from purchase histories to online vendors, either directly through interaction with the Web site, or indirectly through marketing intermediaries, it is possible to tailor offerings more directly to individual buyers. Dynamically constructed pages can reflect customer information and preference in what some call a one-to-one marketing relationship. In addition to personalizing the interaction to enhance the relationship with customers, the two-way interaction supported by the Web, coupled with back-end intelligence about what features and accessories go with selected products, provides the potential for product customization. Many e-commerce vendors offer customers a "build-to-order" option that allows some degree of customization of the products to suit buyer tastes. This is common for computer vendors, but other types of e-commerce companies have also used e-commerce to offer this value-added service to customers. Lands' End, for example, offers hem-to-order pants. Even Levis, in their initial foray into e-commerce, attempted a "made-to-measure" blue jean product.

Collective intelligence mined from data on the population of customers further adds to online merchants' abilities to meet customer needs through sophisticated recommendation systems (Schafer, Konstan, and Riedl 2001). Recommendations can range from using simple automated rules to suggest related products that can complement a product in a customer's order—often termed "cross-selling"—to more complex mining techniques that integrate customer purchase histories, the profiles and purchases of other customers, and association rules. This latter technique, often termed "collaborative filtering," can lead to ever more accurate recommendations as the population of buyers grows larger. Amazon was one of the first to implement such a service with their now famous recommendation services for related books. Such systems can also enhance up-selling practices, where more expensive alternatives are suggested.

Incentive and Loyalty Programs

In an effort to inspire greater customer loyalty, many e-commerce sites followed the lead of airlines and offered

various types of incentive marketing programs. Frequent shoppers can accumulate points on many sites that entitle them to discounts and other benefits. Because all transactions are automated and it is so easy to collect information via the Web, these types of programs became much more accessible to all online merchants. As with airline frequent flyer programs, these techniques create switching costs, since customers who do not return know they will lose accumulated benefits.

Direct E-Mail, Viral, and Multichannel Marketing

The Internet affords merchants new channels with which they can interact and sell to consumers, even beyond their own Web sites. For example, e-mail, the most popular application of the Internet, has been a valuable e-commerce marketing tool. Companies obtain e-mail addresses of visitors and customers, and regularly send targeted letters with new product information, announcements of sales, and other promotional content. Although diminished in usefulness today because of the overwhelming presence of spam, customers may still opt-in to receive information on product updates via e-mail.

Perhaps more important than direct e-mail from merchant to consumer is the interaction between customers that can be facilitated in the online context. Increasingly, companies rely on customers to help spread the word about their products and services. Such a strategy is known as viral marketing, because the marketing material is carried by customers and spread throughout a target population. Often, dissemination is accomplished by giving users access to free services or games, which require the participation of others. Paypal, for example, lets its customer send payments to others for free. Recipients must open an account with Paypal in order to transfer the funds into their regular bank account. This strategy has helped grow the number of Paypal account holders, which in turn entices more merchants to accept Paypal payments. Merchants, however, do pay a fee to receive funds.

Such customer-to-customer interactions may also occur in new social network communities, perhaps with some sponsoring activity by vendors. Online social network services like MySpace and Facebook enable users to construct rich profiles and then to make explicit connections (friends) with other site users. These so-called articulated friendship networks (Donath and Boyd 2004) are visible, so one user can see his or her friends' friends. This can help foster new connections and help users judge someone they do not yet know based on the implicit warranting done by mutual acquaintances. E-commerce companies have discovered that such online social networks can be valuable marketing tools, for purposes such as viral marketing campaigns, obtaining product feedback from user discussions through sponsored groups, or simply mining profile data to better target product advertising.

Channels to reach potential buyers can extend to other online business, in what have been called "affiliate relationships," as well as into the offline world. In the former situation, vendors use the wider Web community to help

sell products. This involves more than simple reciprocal linking, and can include payments to Web affiliates that refer a customer who purchases a product. Amazon was a pioneer in this area as well, allowing virtually anyone with a Web site to become an Amazon affiliate. For example, an author might provide a link from his or her personal Web site to the book's purchase page on Amazon. The link is coded to identify the referrer, who then earns a slight commission on any purchase originating from the referring site. Multichannel e-commerce extending to the offline world has expanded considerably in the past decade. In most cases, these retailers have both a physical store and a virtual one, and seek to meet diverse customer needs with this combined offering. For example, a multichannel—or click-and-brick—retailer can provide detailed product information online, immediate pick-up in a store, and extensive support after the purchase online. Catalogue companies can refer to their Web site in every printed catalogue mailed to customers. In this way, they can gain the benefit of a regular reminder to look at their merchandise, with the cost savings that accrue when customers fill out online forms instead of calling a call center. Such examples highlight how click-and-brick firms and catalogue companies capitalize on the synergies that arise from the integration of traditional and online channels (Steinfeld et al. 2002; Steinfeld 2006). Such synergies may not come without problems, as channel conflicts may surface, in the form of undue competition across channels, cannibalization of sales, and lack of seamless interoperability that frustrates customers.

BUSINESS-TO-BUSINESS E-COMMERCE

Although business-to-consumer (B2C) e-commerce captures much of the headlines, business-to-business e-commerce volume is vastly larger—representing 94 percent of all U.S. online transactions in 2003, as noted earlier.

B2B e-commerce typically is divided into two main categories based on characteristics of the infrastructure and interfirm relationships of the participants: private industrial networks and Internet-based marketplaces (Laudon and Traver 2003). Private industrial networks are typically organized over proprietary network arrangements and involve existing trading partners in established trading relationships. Internet-based marketplaces rely on public network arrangements and hence can be open to new participants.

B2B Internet marketplaces have further been classified according to two important dimensions of business purchasing: how businesses buy and what businesses buy (Kaplan and Sawhney 2000). The "how" dimension distinguishes between spot purchasing to fill an immediate need, and systematic purchasing for planned, long-term needs. The former is often done using ephemeral, market-based transactions, without long-term contracts. The latter is often done after significant negotiation, and is often used for purchasing in large volumes from trusted trading partners. The "what" dimension normally distinguishes between vertical (also called "direct" or "manufacturing") inputs that relate to the core products of a firm and horizontal (often called "indirect" or "MRO")

[for maintenance, repair, and operating]) inputs, such as office supplies, that are acquired by all firms.

Laudon and Traver (2003) distinguish the following four types of Internet-based B2B marketplaces.

- E-distributors (support spot purchasing for horizontal inputs), such as Grainger.com or Staples.com, offer electronic catalogues representing thousands of suppliers. Laudon and Traver (2003) call them the Amazon.com for industry since they operate much like retailers. The main benefit for buyers is simply the reduced search cost, although additional services such as credit and account management are offered to help further reduce transaction costs.
- E-procurement services such as Ariba.com also offer MRO supplies, but focus on systematic purchasing rather than spot purchasing. Such B2B intermediaries offer a range of procurement services, including the licensing of procurement software that supports a range of value-added services. They do not own the supplies, but offer the catalogues of thousands of suppliers from whom they also obtain fees and commissions. They theoretically bring value by aggregating both buyers and sellers, decreasing search costs for both parties, and therefore are subject to significant positive network externalities (the more buyers they attract, the more suppliers will join, and vice versa).
- Exchanges, such as E-steel.com, are intermediaries that focus on bringing together buyers and sellers within a particular industry, and concentrate on the spot purchasing of manufacturing inputs. They charge commissions, but offer a range of purchasing services to buyers and sellers, supporting price negotiations, auctions, and other forms of bidding in addition to normal fixed-price selling. Buyers benefit from greater choice and lower prices, while sellers gain access to large numbers of buyers. Often these vertical markets are used to unload surplus materials (for example, via auction). They are also subject to network externalities.
- Industry consortia are best represented by Covisint, the electronic procurement system developed by the leading automobile manufacturers. These exchanges are typically jointly owned by large buying firms seeking to rely on electronic networks to support long-term relationships with their suppliers. Entrance is by invitation only, and the buying clout of the founders influences suppliers to make the investments needed to participate.

In general, Laudon and Traver (2003) note that private industrial networks remain far more commonplace than Internet-based B2B markets. This is perhaps due to the need to make investments in the hardware, software, and business process re-engineering necessary to accomplish B2B transactions electronically. Companies need to be sure there is a payoff for these investments, and hence engage in them to serve established trading partners (Kraut et al. 1999). Moreover, as e-commerce becomes a more important part of the supply chain, greater amounts of strategic information (e.g., provision of forthcoming product designs to help suppliers prepare for new orders

and better integrate their components), then concerns over the protection of information, lead firms to restrict electronic transactions to trusted trading partners.

ONLINE CONTENT DISTRIBUTION

The content industries have been dramatically affected by e-commerce. Because content today is created, stored, and increasingly distributed digitally, it is ideally suited for e-commerce. Content is a classic example of an information good, with its unique economic characteristics (Shapiro and Varian 1999). It is unrivaled in that consumption by one user does not necessarily prevent consumption by another. Content producers traditionally face high first-copy costs for quality content, but near-zero marginal costs of digital reproduction and dissemination. These characteristics can encourage illegal copying and piracy, which can ultimately result in lower incentives to produce good content. New strategies are required, therefore, of content producers, since the Internet could easily render older business models obsolete (Evans and Wurster 2000). Online content business models are appearing, including on-demand (e.g., iTunes), subscription (e.g., Rhapsody), advertiser-supported (e.g., New York Times Electronic Edition), and various combination models (e.g., free or advertiser-supported basic content with premium paid content). The content industries face many challenges related to e-commerce. First, because of the legacy expectation that content on the Internet should be free, many content providers, especially in the online news arena, have felt compelled to find ways to provide online content without subscription or per-use charges. In the case of newspapers and magazines, this means that companies face the risk that online versions will cannibalize sales of offline subscriptions. The empirical evidence is mixed on this topic. Simon (2005) found that magazine subscriptions decline by 3 percent following the introduction of a Web site, while Kaiser and Kongsted (2005) found a complementary effect, with offline circulation increasing following the establishment of a companion Web site.

Content producers and distributors also face severe challenges from piracy, especially in the context of peer-to-peer file-sharing services (Premkumar 2003). Premkumar noted in 2003 that more than half of all U.S. teenagers had downloaded free music over the Internet. Today, the availability of legitimate Internet-based on-demand and subscription-based services offering music, TV shows, and movies, coupled with aggressive prosecution of copyright violations has alleviated the damage to some extent. Digital rights management (DRM) software is used to limit consumers' abilities to upload online-purchased digital music to free filesharing sites. Yet it also limits consumers' abilities to use their purchased content on multiple devices, creating some backlash against the DRM schemes in use.

Another new development facing content producers seeking to make gains from e-commerce is the rise in user-generated content. Some news-related weblogs (blogs) and video weblogs (vlogs) have become quite established, attracting many readers and viewers (Rainie 2005). User-generated video is also increasing in popularity, with a

number of sites appearing that aggregate online user-generated video into new Internet “channels,” such as YouTube (www.youtube.com), iFilm (www.ifilm.com), and Democracy (www.getdemocracy.com). These sites compete for viewers’ attention, potentially taking revenue from traditional content producers and distributors.

However, established TV and movie producers are increasing their use of the Internet and finding ways to generate new revenues. They are placing trailers on free sites to help promote their content, and rather than make the same mistake as the music industry did, are beginning to embrace the Internet for legitimate purchases. For-pay downloads of video content are provided through online stores such as iTunes, or movie distribution sites such as CinemaNow. Revenue models are evolving beyond one-time purchase and ongoing subscription to also include time-limited rentals using DRM software. Content distribution is also extending to mobile devices as well, using services such as Verizon’s VCast and other mobile content platforms. Sites that host user-generated content are also being viewed as sources of new talent by traditional content providers. Some merchants have even experimented with user-generated ads for their products, not only showing them online, but through mainstream media as well. These new strategies highlight the increasing convergence between old and new media.

ECONOMIC IMPACTS OF E-COMMERCE

Research on e-commerce has identified a wide range of economic impacts that stem from the new business models, costs of accessing customers and markets, supply-chain integration, and marketing and pricing strategies. One recurring theme found in the literature on e-commerce is the potential that it offers for a dramatic reconfiguration of the value chain in industry after industry. Reduced costs for accessing consumers can encourage producers to bypass middlemen, resulting in disintermediation. Online retailers may bypass traditional wholesalers and distributors and work directly with manufacturers. A second recurring theme is the effect of e-commerce on information asymmetries that formerly characterized many markets. Both of these themes are played out in the effect of e-commerce on market structures and prices, on relations between buyers and sellers, on pricing strategies, and on online merchants’ abilities to establish trust. A brief overview of e-commerce research on these topics is provided below.

Effects on Markets and Prices

E-commerce research has long focused on the ways it may influence markets, such as encouraging the bypass, or disintermediation, of traditional middlemen, and altering buyer-seller relations, and creating downward pressure on prices in general. One of the key mechanisms behind these hypothesized impacts is the effect of e-commerce on the costs of doing business. E-commerce helps companies reduce costs and enable the entry into new markets by reducing what economists call transaction costs (Williamson 1975, 1985). Every commercial exchange, including those between consumers and businesses, and

business-to-business exchanges, is a transaction that can be broken into a number of discernible stages, each with its own set of costs to the participants. At the simplest level, we can consider any purchase to require an information or prepurchase phase, a purchase phase, and an after-sales, or postpurchase phase. During the information phase, for example, buyers face search costs, while sellers have costs to supply purchase information to buyers. During the purchase phase, other costs are associated with negotiation, monitoring contracts, and actual financial settlement. Postpurchase costs include repairs, returns, and other types of customer services. When transaction costs get too high, markets become inefficient, and prices can be higher than they should be. For example, imagine a small town with one seller of some product. Without the Internet, customers in this town face high search costs (e.g., driving to another city to look in stores there) with uncertain payoff. So they pay the higher prices charged by the local monopoly provider. With the Internet, customers’ search costs for finding lower-priced suppliers are dramatically reduced, forcing the local monopoly seller to lower its prices. Because of this effect, many economists believe that the Internet will help reduce prices across all industries (Bakos 1997). Indeed, it became popular to talk about the “death of distance” as a barrier to commerce due to the reduced transaction costs afforded by e-commerce.

One oft-mentioned market structure impact of the reductions in transactions costs offered by e-commerce is its potential to enable producers of goods and services to bypass intermediary firms like wholesalers and retailers and sell directly to end customers (Benjamin and Wigand 1995). Many producers were swayed by this logic, and began to sell products directly from their Web sites. For some companies, such as Dell Computer and Cisco, the direct-sale business model made a great deal of sense, and the Internet provided a cost-effective way to manage it. Most of their customers were businesses already connected to the Internet, and accustomed to doing business in this way. For others, especially those selling to consumers, this approach made less sense. Sarkar, Butler, and Steinfeld (1995) showed early on that, in fact, the Internet provided as much or more opportunity for new forms of intermediation, and also helped to strengthen the role of existing intermediary firms. Indeed, some of the most famous Internet companies, such as Amazon and eBay, are examples of the new types of intermediation made possible by e-commerce. Sarkar and colleagues argued that intermediaries’ transaction costs have also been reduced, and the gains they get from e-commerce may negate any advantages producers might gain. They also note that intermediaries provide many functions to both buyers and sellers, such as needs assessment and evaluation, market information, and risk reduction, which are critical for many purchases. Many subsequent analyses demonstrated the fallacy of the disintermediation hypothesis (e.g., Schmitz 2000). Marketing theorists caution that while any particular intermediary might be eliminated, their functions cannot be, suggesting that a role remains for intermediaries even in the age of e-commerce (Stern, El-Ansary, and Coughlan 1996).

Buyer-Seller Relations

Another market effect of e-commerce related to transaction costs in general, and search costs in particular, is the potential for companies to find new trading partners rather than remain locked in to existing relationships. If transaction costs can be reduced, then market mechanisms may be used where they were not feasible beforehand, based on an early theoretical argument proposed by Malone, Yates, and Benjamin (1987). For example, suppose a company needed a very specific type of input, available from only one particular supplier in its area. In the past, this company was at a disadvantage. Because of information asymmetries (the supplier knew what it cost to make the goods, but the buying company did not), and lack of alternative providers, the supplier could charge higher prices. However, the reduced search costs and greater information available on the Internet reduce these asymmetries, and increase choice. Hence, firms can avoid being locked into long-term relationships, and use more spot-market buying behavior to source the inputs they need. The theoretical prediction was that such uses of e-commerce would give rise to large electronic marketplaces in which businesses could buy inputs based purely on the best available offers.

Although e-commerce did result in the formation of large B2B electronic marketplaces that offered both manufacturing (vertical) inputs and commodities (horizontal) supplies, the above prediction has not been entirely supported. First, most of the third-party developed B2B markets have failed (Laudon and Traver 2003). Substantial empirical evidence suggests that firms are more likely to use e-commerce to increase the efficiency of transactions with trusted suppliers than to enable spot transactions with new suppliers (Steinfeld, Kraut, and Plummer 1995). Hence, they were less likely to allow new third-party firms to position themselves as profit-making intermediaries in these well-established relationships. Instead, the bulk of B2B e-commerce occurs over private industrial networks typically organized by larger buyers or sellers. Often a large company will function as the leader in a value network that encompasses firms up and down the value chain. These value networks compete with other value networks, as an extension of simple firm-to-firm competition. The B2B e-commerce links permit more than just simple buy and sell transactions—they enable collaborative e-commerce among networks of firms, allowing activities such as co-design of components, joint marketing efforts, and the like.

Pricing

As noted above, because of the reduction in transaction costs, and access to information about prices of alternative vendors, a primary effect of e-commerce was supposed to be lower and more homogenous prices relative to traditional channels. Up to now, the evidence for lower prices is rather mixed, especially when the added costs for shipping are taken into account. Moreover, price dispersion remains high, contrary to the expectations of economists (Smith, Bailey, and Brynjolfsson 2000). It appears that because it is so easy to change prices (referred to as menu costs), Internet companies make more changes in smaller increments in order to respond to the market.

Another reason there is variability in prices is that e-commerce makes it easier to engage in price discrimination, whereby vendors sell the same product to different customers at different prices. The goal, of course, is to learn what each customer is willing to pay, and then charge him or her that price. One way that this can happen is through auction pricing, which allows customers to submit their willingness to pay in the form of bids. Another popular price-discrimination approach is to charge different prices for different versions of the same product or service (e.g., a student version of software vs. a professional version) (Shapiro and Varian 1999). Sometimes e-commerce companies have tried to estimate willingness to pay based on some aspect of online behavior. Amazon, for example, once angered its customers when it was revealed that the online vendor had attempted to charge higher prices to returning customers, based on the assumption that these loyal customers would be less likely to switch to other online sellers. They soon stopped this practice. Another method of price discrimination is to make assumptions about willingness to pay based on the referring site. Thus, if a shopper arrives at an online retail site by way of a comparison shopping agent or a discount shopping site, he or she may be presented with a lower price than a shopper who had clicked on an ad in an upscale investment journal.

In summary, much of the market impact literature related to e-commerce overlooks many important influences on the price of any product, including the fact that online products differ in many ways from their counterparts in a store. Online products are not immediately available, cannot be touched, smelled, or otherwise physically examined, and perceived risks—for example, ease of returns—may be higher. It further ignores the importance of established relations between buyers and sellers, as well as the use of e-commerce in ways that lock in trading partners rather than reducing so-called market frictions that make it easier to switch vendors. For example, companies that gather information from customers, and then use this to help offer highly personalized services, or that provide incentives to keep customers returning to their Web site, create what has been called “sticky” e-commerce (Shapiro and Varian 1999). In this way, e-commerce raises customers’ switching costs (the costs to move to a different supplier of a good or service), raising a new barrier that can help prevent other firms from successfully attacking a particular market. Network externalities, which create positive feedback loops so that the larger the service, the more attractive it is, also work to make it difficult for new firms to attack established players. For example, eBay is so attractive because its large user base increases the likelihood that people can always find the specific product they are seeking. This in turn draws more sellers, which attracts more buyers, and so on. Smaller systems have trouble competing with this dynamic. Such differentiation effects demonstrate that e-commerce does not make exchanges frictionless, and this result would not, in any case, be in the interest of merchants.

Alternative perspectives point out other reasons why new entrants may find it difficult to dislodge incumbents in any industry. Afuah and Tucci (2001) point out that incumbent firms normally possess crucial resources

that new entrants may not have. These are often called “complementary assets,” and include factors such as established relationships with suppliers, experience, access to retailers, powerful information systems, and strong distribution networks. Indeed, the rise of click-and-brick e-commerce show forcefully how incumbent retailers can better capitalize on e-commerce than the new dot-coms that do not possess the required complementary assets.

Trust, Security, and Privacy

How to establish trust in online commerce is one of the most heavily researched e-commerce areas, becoming an issue when thousands of new and unfamiliar dot-com companies flooded the Internet (Grabner-Kräuter and Kaluscha 2003; Koufaris and Hampton-Sosa 2004; Tan and Thoen 2002). Consumers are reluctant to shop at unfamiliar online stores for fear that their orders may not be fulfilled or that they may not be able to return defective merchandise. The same problem prevents businesses from buying from unfamiliar suppliers, who have not proved that they are both trustworthy and competent to handle the business. Much of the research has attempted to identify factors that influence the formation of trust, such as Web-site quality, presence of Web assurance seals (verification from trusted third parties—firms like VeriSign or Trust-E that vouch for the legitimacy of an online vendor), use of secure servers for transactions, and specification of privacy policies (Kim et al. 2004). To some extent, the growing familiarity of e-commerce brands, and movement of established firms into e-commerce has helped. However, consumers have new concerns about how e-commerce companies will use the information they collect. This is a privacy issue on its face, but also reflects a lack of trust that online vendors will behave responsibly.

A related issue is the fear that many online users have over the security of online transactions. Theft of credit-card numbers and personal information are chief concerns, and statistics on online fraud supplied by the Federal Trade Commission (2004) suggest that trust and security remain a significant problem. Clearly, the continued use of strong encryption measures, such as those outlined above in the section on “Encryption Methods in E-Commerce,” will help bridge the trust gap. Secure transactions are not enough; they must be accompanied by sound information security practices in all aspects of a firm’s infrastructure. The cases of hackers breaking into corporate networks and stealing entire databases of credit-card numbers stored on servers reminds us of the importance of an overall information security policy (Laudon and Traver 2003). Other measures for establishing trust, however, are also needed for consumer-to-consumer markets like eBay, as noted above. Reputation and feedback systems, as well as escrow systems, are some of the measures used to generate trust among strangers in such auction markets (Resnick et al. 2000).

Finally, for many purchases, e-commerce may not be the best approach, given consumers’ needs, desires, or home situations (Steinfeld et al. 1999). For example, when someone needs a product immediately, they are much more likely to pick it up at a local store than wait

one or more days for delivery. Click-and-brick firms such as Best Buy recognize this need, and now offer in-store inventory search and pick-up options for online shoppers. Other consumers see shopping as a social and entertainment activity, and a visit to the mall with friends is hardly replaceable by e-commerce. Finally, some services simply require too much of consumers to be viable. For example, in order to buy groceries including perishable items online, someone needs to be home at the time of delivery. This scheduling may be difficult, and to get around it, some companies attempted to use refrigerators in garages to which deliverymen had access. Yet this also requires consumers to open up their private space to strangers, and the costs of installing appliances at customer premises proved to be impractical. Moreover, not everyone had a garage, which limits the market. These are just a sampling of shopping situations in which e-commerce might not be the best option.

CONCLUSION

This chapter has provided a broad overview of e-commerce and showed how the creation of a ubiquitous, easy-to-use, and open data network helped e-commerce emerge as a powerful force from the many precursor systems and technologies. As evolving technologies such as broadband access via wired and wireless networks, new markup standards, encryption systems, and new interfaces, extend the reach of e-commerce, its influence on the structure of commerce throughout the world grows stronger. E-commerce is continuing to spread throughout the economies of the world, with the pace determined by national policy contexts, infrastructure availability, and cultural factors.

The dot-com bust may have caused some to be pessimistic, but it can also be viewed as a normal evolutionary process at the start of any new industry. Poor business models have failed, but viable ones have survived and are now prospering. Moreover, the entry of established companies into e-commerce is lending more legitimacy to the sector, and is helping to overcome trust problems, as is the increasing use of powerful public key encryption systems to protect transaction data. These firms also have the resources and alternative sources of income to enable their e-commerce channels to develop appropriately, without reckless moves aimed at capturing market share at the expense of profits.

Online commerce fundamentally changes businesses practices in many industries, enabling customization where it was not possible before, creating long-tail markets for goods and services that could not previously be offered in a profitable way, and opening up markets to new competitors coming from different locations and industries. Value chains are experiencing reconfiguration, as the costs of reaching suppliers and customers are reduced and information asymmetries lessened. Efficiencies in the supply chain encourage globalization, and lower prices for consumers.

As e-commerce becomes even more pervasive, new research issues continue to surface. The extension of data capture through mobile devices, for example, requires much new work on how to provide services without

intrusions into personal privacy. The increasing sophistication of pricing strategies requires greater understanding of their effects on both sellers and buyers. The growth of multichannel retailing requires more understanding of how to manage channel conflicts and identify synergy opportunities. New interface techniques are being deployed without adequate understanding of their effects on users. The implications of new online practices such as mash-ups, user-generated content, and social networking services for e-commerce are not fully understood. Clearly, there is a rich future for research in the broad new field of e-commerce.

GLOSSARY

B2B Electronic Hub: Electronic marketplaces in which business buyers can acquire goods from suppliers. Vertical hubs focus on the provision of manufacturing inputs bringing together firms operating at various stages inside a particular industry value chain. Horizontal hubs focus across industries, bringing buyers and sellers of a wide range of maintenance, repair, and operation goods (MRO) to the market.

Collaborative E-Commerce: A form of B2B e-commerce among cooperating networks of firms that involves more than just purchases, but also such activities as the co-design of components and joint marketing efforts.

Complementary Assets: Resources possessed by a firm that enable it to take better advantage of innovations such as e-commerce. These resources include established relationships, product know-how, existing business processes and systems, and distribution systems.

Disintermediation: An effect of e-commerce whereby producing firms bypass traditional intermediaries in order to sell directly to end consumers. Hence, intermediaries such as wholesalers or retailers (see below) find their position in the market, and thus their very survival, threatened.

Dot-Com: A name given to Internet companies because their network name ended in “.com.”

EDI: Electronic document interchange, a standard for transmitting business documents over computer networks.

Intermediary: An entity that facilitates trade between buyers and sellers in markets. Wholesalers and retailers are considered to be intermediaries that help manufacturers sell their products to end consumers. Real estate agents are intermediaries who bring together home buyers and sellers.

Internet Business Model: A generic term referring to a variety of specific methods of doing business and generating revenue on the Internet.

Network Externalities: A term describing the changes in benefit that an agent receives from a good or service due to changes in the number of other people using that good or service. The word *externality* implies that these benefits are not “internalized” by the seller (i.e., captured in the price). They may be negative (e.g., congestion effects) or positive (e.g., more potential contacts). Often the term *network effect* is used to refer to the increasing benefits to customers associated with a larger user base in an online business.

Price Discrimination: A pricing strategy whereby vendors sell the same product to different customers at different prices in an attempt to maximize overall revenue by matching prices to customers’ willingness to pay.

Public Key Encryption: An asymmetric method of encryption that requires two separate keys: one public and one private. Data encrypted with a public key can be decrypted only by the corresponding private key, and vice versa. Asymmetric systems are in contrast to symmetric, or private, key systems, which use the same key at both ends to decrypt transmissions. Public key systems solve the problem of sending keys over an insecure network, and they are often used in concert with symmetric systems—encrypting the symmetric key prior to sending to the other party.

Switching Costs: In e-commerce, such costs are the additional costs a user (or buyer) faces when changing to a different supplier of a good or service, caused by such factors as learning costs, loss of accumulated benefits, contract requirements, and so forth.

Transaction Cost: Costs incurred by buyers and sellers as they complete a commercial exchange, including search and information-gathering costs, monitoring and settlement costs, and after-sales and service costs.

INTRODUCTION

Electronic data interchange (EDI) is the exchange of business transactions from computer to computer using standardized formats. EDI usually involves an electronic link from one organization to another, but it can also be used for transactions from one division of an organization to another division of the same organization. EDI is classified as a type of interorganizational information system (IOIS). There are more than 100,000 companies in the United States (Cooke 2002; Witte, Grunhagen, and Clarke 2003) and more than 200,000 worldwide (Angeles et al. 2001) using EDI. The U.S. Census Bureau reported that for the year 2000, manufacturers were the largest business users of electronic commerce, conducting 18.4 percent of their orders as electronic transactions.

EDI is a form of business-to-business (B2B) electronic commerce, and is considered one of the earliest forms of e-commerce. B2B is the largest portion of electronic commerce. Some studies have reported that EDI accounts for over 80 percent of B2B electronic commerce (Down 2002; Laudon and Laudon 2006).

EDI processing involves the translation of transactions into standard EDI formats. These formatted transactions are sent electronically to a trading partner, and the trading partner translates the transactions from the standard format into the format required for processing by its systems. EDI started in the early 1970s, when the transportation industry created the Transportation Data Coordinating Committee to develop standards for forty-five common types of transactions (Hsieh and Lin 2004). The earliest forms of EDI used private networks to link with trading partners, in some cases going through value-added network (VAN) service providers. The availability of the Internet has motivated organizations to move much of their EDI traffic to the Internet to reduce

communication costs. It is estimated that Internet EDI transactions are increasing at an annual rate of about 50 percent (Zuckerman 2004).

EDI is an enabling technology: it enables businesses to send and receive business transactions electronically. EDI not only results in greater accuracy and faster processing of transactions, but it can also permit the full business-to-business integration of information systems. Researchers have observed that the use of EDI has revolutionized the ways in which organizations conduct business in recent years (Arunachalam 2004; Lee, Lee, and Kang 2005). EDI is moving beyond dyadic (between two trading partners) implementations and toward networked configurations (Arunachalam 2004; Christiaanse 2005) that enable even greater levels of benefits.

BUSINESS APPLICATIONS OF EDI

The business applications of EDI have increased as EDI has grown and evolved. Like other applications of computer technology, EDI started out as an efficiency improvement. The number of types of transactions defined by EDI standards has increased since its introduction. Its role in business has similarly expanded. This section explains how the motivation for businesses to use EDI has changed since the inception of EDI, and identifies the ways in which EDI can support various business strategies.

Motivation for Using EDI

EDI began at a time when computing technology was mainframe-based and proprietary; few common communication protocols existed among vendors, and data representation also varied by vendor (Hsieh and Lin 2004). Companies did recognize the limitations of paper-based

transaction systems (Down 2002): it is labor-intensive and inefficient; it does not permit easy tracking; it requires long lead times for processing; there are many opportunities for errors; it may require data entry multiple times for the same data; and it does not provide visibility into the process. EDI evolved as a way to overcome these problems. The first industries to develop EDI solutions were those with high volumes of transactions: transportation, automotive, grocery, and retail (Hsieh and Lin 2004; Witte et al. 2003).

The early EDI adopters identified standards for common types of transactions such as shipping notices, orders, and other transactions to support trade, and invoices, payments, and other financial transactions. Many of the reasons for initially adopting EDI were to improve efficiency. Some small and medium-size businesses have adopted EDI as a requirement for doing business with a larger trading partner (Hart and Saunders 1998; Iacovou, Benbasat, and Dexter 1995). Today, EDI is frequently used to support business strategies such as just-in-time (JIT) inventory management and continuous replenishment process (CRP), and is important in supply chain management (SCM). The motivation for using EDI now extends to integrating business processes and optimizing business operations (Arunachalam 2004; Down 2002).

Business Strategies Supported through EDI

EDI can be applied to many functional areas, from logistics to management (Hsieh and Lin 2004). Banerjee and Kumar (2002) identify the following business objectives that can be supported through the use of electronic business data interchange: reduced raw material inventory, reduced finished goods inventory, reduced cost of quality, reduced shipping costs, improved cash flow, increased sales opportunities, reduced data entry and paper costs, improved customer service, and faster response to changing product demand. Companies frequently initiate EDI to support JIT inventory management systems (Hsieh and Lin 2004), which can lead to reduced inventories.

Campbell used EDI to support a CRP strategy with the grocery retail chains that it supplies (Lee, Clark, and Tam 1999). Although Campbell had previously used EDI with the retail chains, the chains managed their own inventories. Under the new system, Campbell managed the inventories, a major change for the business. The arrangement led to improved inventory turns and reduced stockouts for the retail chains, and improved sales for Campbell.

Smaller companies may be coerced into using EDI in order to satisfy the demands of a larger company that they supply. For these companies, using EDI may be a necessity to ensure survival. Companies should plan their EDI implementations with trading partners in order to avoid alienating them (Iacovou et al. 1995). Research has found that the level of trust in trading partner relations is positively correlated with successful EDI implementation (Ruppel, Underwood-Queen, and Harrington 2003). Hart and Saunders (1998) found that companies that used cooperative strategies and built trust in trading relationships experienced a greater volume and variety of EDI transactions than companies that used coercion.

Companies may need to provide technical assistance to trading partners to help them implement EDI (Iacovou et al. 1995; McGowan and Madey 1998).

The use of the Internet for EDI has led to new opportunities for EDI applications. Traditionally, EDI has been used primarily to support dyadic trading relationships, ones in which a company buys a product from one of a handful of suppliers (Choudhury 1997). EDI can now be used to support highly coordinated trading communities (Arunachalam 2004; Christiaanse 2005; Down 2002; Elgarah et al. 2005) instead of being limited to dyadic trading relationships. The chemical industry is using EDI to support marketplaces and hubs within the industry, enabling companies to connect upstream supply channel functions with channel functions both inside and outside organizational boundaries (Christiaanse 2005). The potential benefits of using EDI are explained in the following section.

ADVANTAGES AND POTENTIAL LIMITATIONS OF USING EDI

There are many benefits that companies have attributed to the use of EDI. However, because some of those benefits are not realized unless a company uses EDI for a high number of transactions, there are some companies whose benefits are limited or go unrealized.

Benefits of Using EDI

Companies have received numerous benefits from the use of EDI. The benefits of EDI include: reduced data entry and paper costs, more timely information, improved information integrity, ability to handle a greater business volume, reduced logistics costs, improved information consistency and integrity, better business communications, improved business processes, and improved security (Banerjee and Kumar 2002; Copeland and Hwang 1997; Hsieh and Lin 2004; Mount 2003; Raghunathan and Yeh 2001; Witte et al. 2003).

Properly implemented, an EDI transaction is entered once by one trading partner and electronically transmitted to the corresponding trading partner. Because the information comes in a standard electronic form, there is no need to re-key the information into the receiving system. EDI often results in more frequent communications with trading partner, which allows faster response to quality problems (Banerjee and Kumar 2002). The electronic transmission is more timely than mail, phone, or fax communications, which EDI replaced. RJR Nabisco reports that its cost to process a purchase order via EDI is only \$1, compared with \$70 for a paper-based purchase order (Witte et al. 2003).

Early EDI systems were targeted toward achieving improved efficiencies through automation of existing processes (Down 2002). The benefits of such systems included reduced transaction costs and improved timeliness of information. Many new implementations of EDI are focused on improving business processes and business operations (Down 2002). Capturing data in electronic form permits businesses to distribute that information to multiple systems for other purposes (Witte et al. 2003).

EDI implementation is a multifaceted concept; one can look at the breadth (number of trading partners using EDI with the organization), diversity (number of different types of EDI transactions supported), and depth (extent to which EDI is integrated with other systems) in measuring EDI implementation (Massetti and Zmud 1996). Some companies have managed to extend integration beyond their boundaries to obtain benefits from EDI. Organizations in some industries have been able to realize network effects by using EDI to more tightly integrate operations across firms, thus extending efficiencies to all participants (Christiaanse 2005).

Potential Problems and Limitations of EDI

EDI has several potential drawbacks: high implementation costs, high operational costs, and the need to keep up with standards or maintain multiple standards (Witte et al. 2003). EDI implementation requires effective controls to prevent intentional or unintentional errors in the system (Lee et al. 2005). Smaller companies may perceive a lack of control in whether or how their trading partners use EDI (Riggins and Mukhopadhyay 1994). New versions of the EDI standards are released every few years, and not all trading partners may upgrade at the same time (Down 2002; Witte et al. 2003). This can lead to difficulties in keeping EDI running smoothly, and adds troubleshooting costs to the costs of using EDI.

The cost of implementing and operating EDI systems can be high (Mount 2003; Witte et al. 2003). Mount estimates that the cost to purchase and install EDI software could cost a mid-sized company \$120,000, and that operation costs, including communications costs for transactions, could reach \$400,000 for a mid-sized company. For companies performing high volumes of transactions, the benefits may far exceed the costs, but they may not for small companies (Down 2002; Lee et al. 2005; Mount 2003). The costs of implementing EDI will vary with the type of technology used (Banerjee and Kumar 2002).

EDI has both administrative and technical components. Organizations that possess greater levels of technical knowledge have been able to achieve greater levels of EDI implementation than organizations with lower levels of technical knowledge (McGowan and Madey 1998). EDI users may fail to realize the benefits of EDI if they do not adequately integrate EDI systems with other systems (Copeland and Hwang 1997). This level of integration may require a company to use business process reengineering to modify the business operations involved with EDI (Lee et al. 1999).

HOW THE EDI PROCESS WORKS

Overview

Recall that EDI is the computer-to-computer exchange of business transactions in standardized formats. The EDI process for a customer sending a purchase order to one of its suppliers is illustrated in Figure 1. Assuming that the customer has already entered the purchase orders into the purchasing system, the first step in the process is for a program to extract and format the purchase order information from the purchasing system. The extracted

Figure 1: Steps in the EDI process

information is then translated into an EDI-standard format, often done by commercial EDI software. Next, the purchase order information, now in the standard format, is packaged for transmission, also frequently done by commercial software. The packaged purchase orders are then transmitted electronically to the supplier. Various communications alternatives are discussed later in this section. The supplier receives the packaged purchase order documents and uses its EDI document management system to parse the packaged documents into their component documents before running them through the translation software. The resulting translated documents are then formatted to match the supplier's order system and loaded into the order system. The entire process is automated and electronic, so there is no need for human intervention.

It is possible to outsource various steps in the EDI process. For example, some customers use a network service provider to perform the translation and EDI document management. Other companies may choose a less sophisticated approach to EDI. Commercial software is available that would allow a customer to enter the purchase order information; the software would translate the information into the EDI standard format and package it for delivery. Similarly, there is commercial software to receive EDI information, parse it into documents, and print the documents. Companies that use this technique often do not receive the full benefits of EDI.

The major EDI standards are discussed later in this chapter. There are two common communications network alternative for EDI: traditional EDI and Internet-based EDI. These two approaches are discussed in the remainder of this section.

Traditional EDI Communications

The earliest EDI communications configurations used proprietary protocols, which meant that EDI could take place only between trading partners with compatible

systems (Witte et al. 2003). Some larger companies established their own systems for processing whereby their trading partners would connect directly to the host company to transmit and receive EDI transactions over dial-up or leased lines. The larger company acted as a hub, and its trading partners would link to it, much as spokes connect to a hub on a wheel (Arunachalam 2004). This arrangement created a problem for trading partners who might need special equipment to communicate using multiple independent spokes to connect to multiple hubs. This led to the development of value-added network (VAN) service providers.

One of the primary services offered by VANs is to serve as an exchange for EDI transactions among various trading partners. The VAN offers electronic mailboxes and distribution services to its customers. A trading partner can send its EDI transactions to the VAN over a communications link. The VAN will store the EDI transactions in the electronic mailbox of trading partners who subscribe to the same service, or forward the transactions to the service provider used by the trading partner. In addition to the electronic mailbox, VAN services can include translation services, connectivity, security, and an audit trail (Copeland and Hwang 1997). The mailbox feature means that a trading partner does not need to have a spoke to each of its trading partners, it needs only one spoke to its VAN service provider. The VAN can also provide immediate notification to companies or forward documents to companies to ensure that event-driven processes run smoothly (Copeland and Hwang 1997).

Traditional EDI has used leased lines or dial-up for trading partners to connect to their VAN service providers. This mechanism replaced the early proprietary systems, in which a large company would maintain its own mailbox system. The growth of the Internet as a ubiquitous, low-cost communications network has led to the development of Internet-based EDI alternatives.

Internet-Based EDI Communications

Multiple technical EDI implementation alternatives are possible through the Internet. There is not a single approach to Internet-based EDI that has become a standard. Some companies have tried to bypass expensive VAN providers by using the Internet to connect directly with trading partners. Since the Internet uses a common protocol, this approach does not carry the burden of supporting multiple proprietary communications configurations that created expense under the original proprietary approaches to EDI. Some companies still value the services provided by VANs, and have migrated their communications with their VAN over to the Internet.

Companies are using various approaches to conduct EDI over the Internet. One approach is to use EDI formats and then transmit them using protocols such as file transfer protocol (FTP) (dmx.com 2002) or electronic mail (Chan 2002). Another approach is having trading partners enter transactions directly into forms (Mount 2003), a technique that is sometimes labeled WebEDI or electronic forms interchange (EFI). Companies also use extensible markup language (XML) (Mount 2003; Zuckerman 2004) for exchanging business documents.

The Internet is becoming the transmission medium of choice for EDI (Zuckerman 2004).

One issue common to all Internet alternatives is that of security. The Internet is a public network. Many companies are using encryption services such as secure hypertext transfer protocol (https) or virtual private networks (VPNs) to limit exposure. Security considerations are discussed further in a later section of this chapter.

Chan (2002) describes a technique for using electronic mail multipurpose Internet mail extension (MIME) protocol and traditional EDI standards to exchange business transactions. This approach involves an additional step at both the sending and receiving ends: the formatted EDI documents need to be converted to MIME at the sending side and back at the receiving end.

Global Exchange Services, a VAN service provider, offers software that allows companies to create forms online for its trading partners to enter information; the form is then converted to EDI format and sent to the company for processing (Mount 2003). Such arrangements can reduce the amount of technical expertise required of trading partners while still providing the benefits of EDI to the company hosting the Web site.

XML has become increasingly popular for exchanging documents over the Internet (Mount 2003). XML is a language that is used to define documents containing data. It separates the structure of the data from the content and display of the data, so it offers significant advantages compared to HTML. XML allows the definition of various document types, and then those document definitions can be used to transmit data over the Internet. XML document definitions could be established containing elements similar to EDI documents.

Similarly to EDI messages, XML/EDI messages could be sent via email, FTP, or other Internet communications protocol (Hsieh and Lin 2004). However, XML is slower than traditional EDI (Witte et al. 2003). Since XML messages are as much as nineteen times larger than traditional EDI messages, the difference is especially noticeable in larger transactions (Witte et al. 2003). Since XML can be read by Web browsers, it is expected that many small and medium-sized enterprises (SMEs) will use Web-based forms to read and create XML/EDI documents (Witte et al. 2003). Another problem of using XML is that most implementations do not use traditional EDI formats (Mount 2003; Zuckerman 2004). Some companies have mandated that their suppliers continue supporting traditional EDI formats (Zuckerman 2004).

EDI STANDARDS

Since EDI involves the electronic exchange of transactions in standard formats, it is necessary to develop standard formats for EDI to take place. Early EDI systems use proprietary standards. Proprietary standards created problems for companies that had to support multiple standards of different trading partners (Chan 2002). In the early 1970s, the transportation industry formed the Transportation Data Coordinating Committee (TDCC) to develop common standards for the industry (Hsieh and Lin 2004). The American National Standards Institute formed the Accredited Standards Committee X12 in

1979, and that group adopted the TDCC standards as the basis for national standards, now referred to as the X12 standards (Hsieh and Lin 2004). The X12 standards are widely used throughout the United States.

The X12 Standard

The X12 standard defines over 100 different types of transactions. The standard specifies the data content, structure, sequencing, and syntax for business transactions. Each type of business document is considered a transaction set. The X12 standard includes specifications for business documents such as invoice, payment order, request for quotation, response to request for quotation, and many more. The organization responsible for managing EDI standards in the United States is the Data Interchange Standards Association (DISA) (www.disa.org). In addition to updating the X12 standards, the organization is also involved with the development of international standards.

The X12 standard specifies data segments, groups of related data elements, for each transaction set. A data segment for a shipping notice could include the data elements related to the shipping address, and another for the billing address. The X12 standard also specifies a data dictionary for each transaction set that defines the exact content of the data elements.

The X12 standard also specifies transmission control standards for the electronic envelope used to interchange data. It is possible to include several types of transaction groups destined for the same recipient in a single interchange envelope. An example of the X12 interchange structure is shown in Figure 2. In this example, a single interchange envelope contains two purchase orders and one invoice grouped together for transmission to the

same destination (customer). The interchange envelope is like a courier envelope that is sent from a source to a destination location; it includes address and tracking information. The envelope contains two groups of transactions: the first group contains two purchase orders, and the second group contains one invoice. Groups of the same type of transaction are bounded by headers and trailers. Similarly, each transaction is delineated by a header and trailer. Only one functional group header is needed for the purchase orders, but each purchase order has its own transaction set header and transaction set trailer to separate the documents. The invoice group has its own group header and footer, and the invoice transaction has a transaction header and trailer to mark its boundaries.

UN/EDIFACT Standards

In 1986, the United Nations created a group to develop international standards for EDI, the United Nations Electronic Data Interchange for Administration, Commerce, and Transport (UN/EDIFACT) (Hsieh and Lin 2004). The UN/EDIFACT standard combined the X12 standard from the United States with the Trade Data Interchange (TDI) standard developed in the United Kingdom (Chan 2002), and includes components similar to the X12 standard. Some users claim that one standard has technical advantages over the other. In practice, many U.S. companies still rely on the X12 standard. However, UN/EDIFACT is in widespread use, and companies that want to compete internationally may need to support it (Witte et al. 2003). UN/EDIFACT is widely used in finance and banking, in transport and logistic chains, and in fast-moving consumer goods, and is recommended by the World Customs Organization for customs documents. There are many companies that support both standards.

Figure 2: X12 EDI interchange structure

Other Standards

The growth of Internet-based EDI has seen the call for new EDI standards. One of the impediments to using XML for EDI has been the lack of standards, or, more accurately, the proliferation of standards (Zuckerman 2004). Although some companies are using traditional EDI standards and simply using the Internet as the communications network, others want to design standards that might be better suited to the Internet.

Today there are efforts to develop extensions to XML that will provide standard mechanisms for XML/EDI. DISA is working to develop extensions, based on the X12 standard, to support XML/EDI. Another standard being developed for EDI is electronic business XML (ebXML). The development of ebXML is being led by the United Nations Centre for Trade Facilitation and Electronic Business (UN/CEFACT) and the United Nations Economic Commission for Europe (UNECE), in coordination with the Organization for the Advancement of Structured Information Standards (OASIS) (Butterly and Misovicova 2006). The ebXML standard may replace UN/EDIFACT in the long term, especially for SME trading partners (Hsieh and Lin 2004). It is already widely used in Europe and Asia, and the U.S. Department of Defense and automobile industry are adopting it (Babcock 2004). One goal of the developers is to develop an electronic exchange standard that would be affordable by both large and small companies, including companies that cannot afford EDI's complexity and expense (Babcock 2004). If this goal can be achieved, it would mean that e-business could be done throughout the world by large and small businesses alike.

Industry Conventions

Although EDI standards specify common formats for transactions, many industries have adopted conventions for how they will implement those standard formats. In some cases an industry may use an older version of the standard to ensure that companies use common conventions (Hsieh and Lin 2004). The automotive, airline, and chemical industries have each developed a set of conventions to specify how EDI standards should be implemented in their respective industries. Having a common understanding of how to implement EDI can make EDI implementation faster and less costly.

EDI IMPLEMENTATION AND BEST PRACTICES

This section provides guidelines for the successful implementation of EDI. Before proceeding with EDI implementation, a company must examine its EDI strategy. More accurately, the company must look at how its information systems (IS) strategy will support its business strategy, and how EDI can play a part. For example, a logistics transport company that has a business strategy to reduce delivery times might implement EDI for customs forms to help support that strategy.

When companies consider using EDI, they should first evaluate the underlying business processes in order to be able to obtain EDI's full benefits (Down 2002). Business

process reengineering may be required. As mentioned earlier, entire industries are changing processes to improve business performance.

Successful implementation relies on the development of strong relationships with trustworthy trading partners. Developing trust with trading partners is important to successful EDI implementation (Ruppel et al. 2003). Traditionally, EDI has taken place between companies that are already trading partners before engaging in EDI between themselves. Companies need to assess the preparedness of trading partners to use EDI. Trading partners in the SME category may need technical, administrative, or financial assistance. Doing business electronically may impose new concerns, and a part of many EDI solutions is a trading partner agreement (TPA) (Down 2002).

Using EDI in certain industries may dictate particular standards and influence the choice of hardware and software. A company that deals with many SMEs may choose to use Web-based forms to reduce the technical complexity for its trading partners.

Companies need to pay careful attention to implementation in order to obtain the full range of benefits possible through EDI (Angeles et al. 2001). Technical details of implementation are important because they affect costs, benefits, and security issues (Banerjee and Kumar 2002). Technical issues of implementation include selecting the EDI technologies, developing the infrastructure to support EDI, and interfacing EDI tools with existing systems.

Companies also need to identify and assess potential security risks. Certain types of data may be more inviting targets, or may result in more severe consequences if compromised. Some trading partners may not have adequate security measures in place. Technical or administrative assistance may be necessary with some trading partners. Companies should promote the benefits of EDI both internally and with trading partners.

Proper administrative and technical security controls need to be included in EDI implementation. User training is often required to prevent accidental errors. System controls should be evaluated and tested prior to implementation and reviewed after implementation.

EDI SECURITY

Since EDI involves both technical and administrative components, EDI security must involve both technical and administrative controls. Research has found that adequate security is one of the factors that contributes to successful EDI implementation by U.S. firms for both domestic and international EDI (Angeles et al. 2001). The discussion in this section provides an overview of the steps necessary to secure EDI applications. For a more comprehensive understanding of EDI and its underlying technologies, the reader should refer to *The Handbook of Information Security* (Bidgoli 2006), which includes a chapter on EDI security and chapters on many of the technologies used to implement EDI.

EDI Threats

The primary threats to EDI systems are: (1) interception (unauthorized access to data), (2) interruption (prevention

of transaction completion), (3) modification (intentional or unintentional loss or destruction of data), and (4) fabrication (fraudulent transactions). EDI data can be intercepted at any point in the EDI process. The greatest interception threats occur when data are in transit, particularly if the Internet is used as the communications network. Data interception can also take place while data reside on a computer accessible to the Internet during the EDI process. The EDI process is also susceptible to interception. Since the EDI process involves multiple software packages and multiple hardware platforms, any one of these components could be attacked or fail.

Modification of EDI data can be intentional or unintentional. Unintentional modifications could include incorrect information coming from the originating system or incorrect extraction and formatting of the data, or errors in transmission. The most likely threats of intentional modification are from people who work with the systems from which the data originate or ultimately reside. Fraudulent transactions are a great threat to EDI systems (Smith 2005). The threat comes from a lack of proper administrative controls and system controls in systems that originate EDI data. The following section suggests some ways to deal with these threats.

EDI Security Mechanisms

There are five general types of security mechanisms for reducing the security risks for EDI systems: access control; authentication (originator and receiver); nonrepudiation (originator and receiver); data integrity (content and sequence); and auditable history/paper trail. The EDI security mechanisms are summarized in Table 1.

The issue of who is able to obtain and view the transaction and under what circumstances is the central focus of access control. Access controls must be in place for: (1) transaction origination, (2) the duration of the transaction transmission, and (3) transaction receipt. Transaction origination and receipt should be restricted

to authorized users or applications. Organizations frequently use controls requiring user identification and a password to gain access to such systems. Encryption is one technique for securing data in transit.

Authentication concerns the verification that a transaction is genuine and authorized. Techniques used for authentication include digital signatures or digital certificates. The use of user IDs and passwords may also be part of authorization. Using acknowledgments of transactions can also help with authentication. Nonrepudiation (of transaction origination) provides the recipient of the message with proof that a message has been sent, and the proof should withstand any attempt by the originator to deny sending the message (Humphreys 1995). Similarly, there is a need for authentication on the receiver side of the exchange so that the receiver cannot deny that it received the transaction. Trading partners can use acknowledgments (and save these) as proof of transactions.

Data integrity means the content and sequence of the message is valid, accurate, and complete. Transmission errors are possible with EDI transactions. It is also possible that someone could tamper with EDI transactions. The EDI transaction process needs to ensure data integrity. The document-handling software that receives EDI messages with traditional EDI can check that the message is a valid EDI message. The translation software can also perform some checking. Some EDI systems are set up to use hash totals that are calculated by the originator and then recalculated and checked by the receiver (Sterling Commerce 2003; Wakszumski 1996).

The last security mechanism that can be used is to ensure there is an auditable history maintained so that one can verify the entire transaction process. This may be necessary for accounting purposes. Since EDI involves electronic exchanges, it offers little in the way of a paper trail.

EDI APPLICATIONS

EDI applications have been in use for more than 30 years. During that time, new standards have emerged and new technologies have been used to implement EDI. The two applications described in this section portray the evolution of EDI applications and illustrate the latest direction in EDI applications.

EDI at Sega

The description of EDI applications at Sega is summarized from a description provided by Cohen (2005). Sega is a maker of gaming software that runs on other manufacturers' game consoles; it first implemented an EDI system in 1994. Sega found that its original system had become obsolete and could not keep up with the 7000 orders per month that came from customers that included Target, Wal-Mart, Toys R Us, and Circuit City. Sega's old system used a slow, 9600-baud modem that could take nearly 2 hours to send order information to Sega's warehouses. Several years before Sega converted its EDI system, it invested in an 18-month project to upgrade to a new version of its EDI system. In 2004,

Table 1: Mechanisms EDI Security

Mechanism	Description
Access control	Limit who is able to obtain and view the transaction and under what circumstances.
Authentication	Verify that the transaction is genuine and authorized by the trading partner.
Nonrepudiation	Validate through undeniable proof that the partner participated in the transaction.
Data integrity	Ensure the content and sequence of the transaction is valid, accurate, and complete.
Auditable history	Maintain a complete record of the transaction process.

before the conversion of the EDI system, information had to be batch loaded into Sega's enterprise resource planning (ERP) system.

The business need that drove Sega to convert its system was Wal-Mart's requirement that it support AS2 (applicability statement 2), an Internet-based EDI standard that uses MIME and HTTP for real-time process-to-process EDI (Down 2002). Sega evaluated various vendors' alternatives and ultimately selected one because it had existing adapters and reusable templates that would reduce the time needed to customize the application. The system was also designed to work tightly with its ERP system, had a graphical user interface, and could break a purchase order from a single retailer into multiple separate orders for different locations.

With the help of its EDI solution vendor, Sega was able to do its initial implementation of the new system in 3 months, including customizing document templates for eight types of documents, and meet the EDI formats required by twenty-five trading partners. By the end of 9 months, Sega had phased in all of its other trading partners. Compared to its previous EDI system, Sega has saved money on transaction costs by eliminating its VAN, improved the processing time for EDI transactions, and achieved tighter integration in its business processes. The new system also had a shorter training time for educating its EDI specialists.

EDI in the Chemical Industry

The description of EDI applications in the chemical industry is summarized from a description provided by Vinas (2005). This example also provides some historical perspective on the development of EDI. Researchers have suggested that this is the direction for future growth of EDI (Arunachalam 2004; Christiaanse 2005).

The chemical industry was one of the first to adopt EDI due, in part, to pressure from the auto industry. The Chemical Industry Data Exchange (CIDX) was formed in 1985 to develop standards for the exchange of data within the industry. Since that time, the group has developed its fourth version of its standards, Chem eStandards, for electronic commerce among chemical companies.

The chemical industry moved to EDI in order to lower costs; many chemicals are commodities and have low margins. The chemical industry is characterized by many chemical companies trading with other chemical companies, a characteristic that made adoption and implementation of EDI less costly and more beneficial. Most chemical sales take place via EDI today, but much of that is Internet-based EDI.

The chemical industry is now moving to Elemica, an exchange formed in the early 2000s, that uses the Chem eStandards. Elemica is a vertical industry hub for the chemical industry (Christiaanse 2005). The collaborative effort has resulted in further efficiencies in industry trading (Christiaanse 2005), and is characteristic of the new EDI configurations. Elemica accounts for about 10 percent of sales within the chemical industry. The industry is considering shifting to XML, but many companies are reluctant to give up their investments in EDI.

CONCLUSION

Electronic data interchange has been in use for over 30 years. Early applications of EDI used proprietary protocols and focused on efficiency improvements. Since that time, national and international standards for EDI have evolved, and new communications technologies are available for implementing EDI network applications. Much EDI activity has moved to the Internet, and Internet-based EDI is the fastest-growing type of EDI. The development of EDI standards and conventions for Internet-based EDI will increase the rate of EDI applications, though EDI already accounts for over 80 percent of B2B e-commerce.

Although EDI offers benefits of efficiency to large users of EDI, smaller companies are also able to benefit from EDI. Companies are using EDI to support a variety of business strategies, including JIT inventory management, SCM, and CRP. Since EDI involves both technical and administrative aspects, companies need to pay attention to technical details of implementation as well as to administrative arrangements. Administrative issues include trading partner agreements, developing trust in trading partner relationships, and reengineering business processes. Ensuring the security of EDI network applications requires both technical and administrative controls.

Traditional users of EDI, such as Sega, are upgrading their infrastructures to obtain greater benefits from EDI, often reducing the costs of EDI at the same time. The chemical industry is at the forefront of EDI. Network applications of EDI in the chemical industry are expanding beyond dyadic relationships to include marketplace hubs that will provide even higher levels of benefits to participating companies.

GLOSSARY

DISA (Data Interchange Standards Association): The organization responsible for the development of EDI standards in the United States.

ebXML (Electronic Business XML): An extension to XML designed to accommodate electronic business.

EDI Electronic data interchange, the computer-to-computer exchange of business transactions in standardized formats.

Internet-Based EDI: The use of the Internet as the communications mechanism for electronic data interchange.

IOIS (Interorganizational Information Systems): Automated information systems that involve information sharing between two organizations.

UNEDIFACT: A set of standard formats for EDI transactions developed by a committee from the United Nations (UN).

VAN (value-added network): A company that provides a network and various other services for EDI.

INTRODUCTION

Throughout the ages, from ancient times to the present, money has played a very important role in the ordinary business of the life of different people. Money can be best defined as “anything that is widely used for making payment and accounting for debts and credits”(Davies 2002). All sorts of things have been used as money at different times in the history of mankind, including amber, beads, cowries, drums, eggs, feathers, gongs, hoes, ivory, jade, kettles, leather, mats, nails, oxen, pigs, quartz, rice, salt, thimbles, umiacs, vodka, wampum, yarns, and zappozats (decorated axes) (Davies 2002). In recent times, we are witnessing the emergence of a more intangible form of money—namely, electronic money. In fact, although much of the money used by individuals in their day-to-day transactions is still in the form of notes and coins, its quantity is minuscule compared to the intangible electronic money that exists only as records in the books of financial institutions. With the progression of technology we can envision a society, in the not-too-distant future, in which physical money in the form of notes and coins will become as obsolete as amber and beads and cowry shells.

In this chapter, we look at electronic payment systems. These systems enable the payment for goods and services over a computer network using some form of electronic money. We begin by identifying the requirements for such systems. We observe that the major technical challenge for developing such a system is ensuring its security. We discuss the different types of electronic payment schemes that are available, identifying, in the process, any special security or network requirement for each. However, we do not cover the different technologies that are used to provide these services. These are covered elsewhere in this book. Interested readers are directed to Volume II, Parts 2 (The Internet, Global Networks, and VoIP) and 3 (Cellular and Wireless Networks), and Volume III, Part 2 (Network

Planning, Control, and Management). We discuss some of the more important commercial/research products available today. Finally, we conclude by providing pointers to some of the resources that are available today to learn more about electronic payment systems.

REQUIREMENTS FOR ELECTRONIC PAYMENT SYSTEMS

Electronic payment systems have more or less the same set of requirements as traditional paper-based systems. The difference is that owing to the unique nature of electronic payment transactions, these requirements impose different types of challenges on the payment system design and the infrastructure support. Security is of paramount importance in electronic payment systems, more so probably than in traditional paper-based system. The reasons for this are numerous. First, a major portion of these transactions is carried out over networks, which are rather easy to eavesdrop on even with limited resources. Thus, confidential financial information may no longer remain confidential if adequate protection mechanisms are not implemented. Second, since the transacting parties can remain faceless, it is quite easy to forge identities of end users and systems in the Internet. Anybody can masquerade as somebody else and continue on a transaction with impunity. Gathering evidence of a crime is, thus, more difficult in such an environment. Third, electronic payments are often carried out over inherently unreliable communication media. This implies that messages that are exchanged for execution of the transaction can be corrupted or altered during transit, resulting in unforeseen results. Last, but not least, electronic payment transactions can span both geographical and judicial boundaries. While this is also possible for traditional payment transactions, the implications for electronic payments are different. It is more difficult

to identify a felon in an electronic payment crime and bring her or him to justice.

We begin by summarizing the requirements for electronic payment systems. These challenges can be categorized as network bandwidth requirements (including availability requirements) and security requirements. We observe that while bandwidth and availability requirements are important issues for electronic payment systems, security requirements by far pose the biggest challenge to the widespread deployment of electronic payment systems. In later sections, as we discuss different types of payment systems, we identify specific challenges for each.

Network Requirements

To increase productivity and competitiveness, financial institutions are increasingly relying on computer networks to connect offices, partners, suppliers, and most importantly, customers. As the volume of financial transaction increases, the payment infrastructure must scale up with it appropriately. Servers must be powerful enough to support the rapidly expanding customer base. Communication channels with higher bandwidths need to be established to support the high volume of traffic. To support the real-time requirements of most financial transactions, networks supporting high transmission speeds are also needed. In addition, any disruption of telecommunications services critically affects financial-services processes. Without telecommunications capabilities being always available most financial services companies will be able to provide nothing better than the barest minimum of services. Thus, network resiliency is an important consideration for the financial sector.

Network availability can be compromised because of failures in the network as well as malicious attacks. The first step toward achieving resiliency is to have redundancy in the network. Redundancy ensures that a single point of failure does not disrupt services. Redundancy is achieved by having multiple routes for network traffic from the source to the destination, multiple telecommunications circuits, and/or alternative communications technologies. Although redundancy ensures a significant degree of fault tolerance, by itself it cannot ensure availability in the face of deliberate attacks. To protect against attacks, diversity needs to be incorporated into the network infrastructure. Proper diversity management can ensure that redundant assets do not share common vulnerabilities, thus protecting a network from intentional attacks. Diversity in the network can be achieved through a number of means—(a) obtaining network services from a number of different providers, (b) including alternative communication means (e.g., wired, microwave, radio wave, or satellite), and (c) providing physically and logically separate routes for a transmission. However, even with these measures, failures can still occur. Thus, the network should be able to recover from these failures in a proper manner. This ensures that the affected financial service is restored after a transient failure. Response time is the most important parameter for recovery procedures. A number of measures can help with the recovery process, including proper network management control and using synchronous optical network technology (see the chapter “SONET/SDH Networks”).

Security Requirements

Need to Ensure Integrity for Payer, Payee, and Payment System

The first major rules of thumb in designing any payment systems is to ensure that (1) nothing happens without authorization, and (2) nothing happens without generating sufficient pieces of evidence. Moreover, technical and legal procedures for dispute handling should be made part of the system.

Ensuring proper authorization by itself is not a very big challenge. All that is needed is a provision for signatures, maybe notarized, at the right place for the authorization to be recorded. (The reader is referred to the chapter “Cryptography” for discussion on techniques for obtaining digital signatures.) This needs to be accompanied by proper identification of the signatory and correct association of the signature to the signatory. (Techniques for authentication and authorization are discussed in more detail in the chapters “Access Control” and “Biometrics”.) However, in the context of electronic payment systems, authentication and authorization is more easily said than done. To begin with, although a digital counterpart of traditional signatures has been available for some time, some with even stronger non-forgeability properties than traditional signatures, the technology and infrastructure for these are not yet widely available. Many communities have yet to establish laws that recognize the validity of such digital signatures.¹ Compounding the problem is the technical difficulty associated with identifying and authenticating the signatory. Users of computer systems remain faceless throughout a transaction. Thus, although it is easy to authenticate the process that is used in the transaction, it is extremely difficult to associate the process with a real-life entity. This implies that it is quite easy for the digital signatory of a document to refute a signature later.

Generating sufficient pieces of evidence for electronic payments is also considerably difficult. This requires a proper audit trail of a transaction to be maintained during the entire transaction life cycle and until such time as it is no longer needed. In addition, we must ensure that such audit trails are not tampered with after generation. This is quite difficult to ensure, especially if we impose the requirement that such audit trails and other associated information may often need to be transmitted over open, unreliable networks. With currently available technology, it is not possible to completely prevent tampering with audit trails. We must accept that there will be times when such tampering occurs. Obviously, this creates a number of technical challenges when disputes need to be handled based on audit-trail data. Thus, in the event of audit-trail tampering, we should be able to detect and prove the tampering. Further, we should have proper contingency plans for such an eventuality. Although the technology to perform these individually has been available for many years, an integrated mechanism that incorporates the

¹Currently, there are only handful of countries that recognize digital signatures as legal. The Digital Signature Law Survey at <http://dsls.law.uvt.nl> provides comprehensive information about countries that have enacted statutes concerning digital signatures or are in the process of doing so.

individual technologies into a cohesive framework that is also supported by proper legal and procedural methodologies is still not widely available.

Privacy for Payer and Payee

The requirement for ensuring payer and payee privacy arises in much the same way in electronic payment systems as in traditional payment systems. Users of the electronic payment system need the assurance that their financial information remains confidential throughout the transaction—that only such information as the user deems necessary to reveal is actually revealed. Further, the user needs the assurance that the recipient does not use the piece of confidential information that is revealed in an improper manner. Each of these requirements is extremely difficult to ensure in the electronic world.

To begin with, many electronic payment transactions are carried over open networks such as the Internet. Such networks are susceptible to eavesdropping. Thus, if appropriate precautions are not adopted, any financial information that is transmitted is available to whoever is eavesdropping. The solution to this problem is to encrypt the information in an appropriate manner before transmission. Many people believe that proper encryption is the panacea for all confidentiality problems. This, however, is not really the case. To begin with, we need to remember that a brute-force approach can always, in principle, break the strongest of currently available encryption technology. This is assuming that there is no hidden trapdoor in the encryption algorithm that makes the technique vulnerable. We can take some solace from the fact that such a brute-force approach is beyond the technical and physical capabilities of even the most powerful. However, we should realize that it is extremely difficult to prove formally that an encryption algorithm is strong. In fact, there is no theory that guarantees the strength of any conventional cryptographic systems. Traditionally, encryption systems have been considered strong when they have been used and tested for a reasonably long time without anybody knowing how to break them efficiently, in a practical and practicable manner. Such testing can prove the weakness of a particular scheme for a given level of effort; this cannot prove that there is no simpler approach to breaking the scheme. In addition, encryption technology is sometimes implemented incorrectly, just as buggy software. Thus, there can be loopholes in the software that performs the encryption operation that can be exploited to breach confidentiality. Ensuring that encryption software is foolproof is not an easy task.

Assuming that we can protect confidential information from prying eyes while in transit, we note that it is extremely difficult to ensure that the recipient treats confidential information in a confidential manner. For example, many of us use credit cards for purchasing services. The merchant stores such credit-card numbers electronically in its computer system. However, there is no guarantee that the merchant's computer systems are adequately protected. Although this is also the case for traditional financial transactions, we at least know to whom we are revealing confidential information. In the electronic world, the end parties are faceless. We may

easily be led to believe that we are revealing information to trusted parties when we are not. In addition, we do not know whether the recipient handles the information in an appropriate manner.

A related problem is how to ensure the anonymity of the user of the electronic payment system. A user may want that not only that his or her financial information remain confidential but also that he or she remain anonymous in the transaction. If a user is using traditional cash in a transaction, the user remains anonymous. It is not possible to link a transaction that has been paid for by traditional cash to a particular customer. It is also not possible to derive any personal information about the customer from this transaction. In the electronic world, this is more difficult to achieve. Part of the reason is that every message that is used in the transaction can be traced to a source address. Complex cryptographic protocols are needed to achieve such anonymity or unlinkability. At the same time allowing anonymity creates additional problems, namely in the way of ensuring authenticity, proper authorization, and fair exchange.

Fair Exchange

In the classical business environment, a transaction essentially involves fulfillment of some obligation by two parties; a contract describes the penalties if either party fails to meet its obligation. Since each transacting party has an identifiable place of doing business, if any party behaves unfairly, that party can be physically approached and held accountable for its unfair behavior. In the electronic world, on the other hand, a party does not always have a physically identifiable place for doing business. After behaving unfairly in the electronic transaction, a party can simply vanish without a trace. In such cases, it may be next to impossible to enforce the penalties of the contract, leading to losses for the other party. For example, a customer buys a product from a merchant. The customer pays for the product in some electronic manner. However, once the merchant receives the payment the merchant never delivers the product. This causes financial loss for the customer. Thus, any electronic payment scheme must ensure that at the end of the protocol execution, either each transacting party receives the other's product or neither does. This is often referred to as the problem of fair exchange, and it is quite difficult to achieve, particularly if this needs to be accompanied by anonymity for the payer or the payee.

In summary, it is fair to say that though electronic payment systems make it easier to perform commercial transactions over the Internet, there are a number of challenges remaining to make the scheme successful. In the following section, we discuss some of the types of electronic payment systems available today. We also discuss some of the challenges unique to each scheme.

TYPES OF ELECTRONIC PAYMENT SYSTEMS

Electronic payment systems broadly use one of three forms of electronic money: (1) token money, (2) notational money, and (3) hybrid money.

Token money is similar to real cash. It is used in token-based or cash-like system. Transactions are performed with token money that has a certain value and must be brought to a central authority before consumers are able to make any transaction. These systems do not support the notion of debt. Electronic cash and electronic purse are the two major types of token money systems.

Notational money is used in credit/debit systems. The system consists of having an account and a central authority keeping a record of the amount in that account. Consumers exchange documents that are equivalent to value transfers. These exchanges consist of debiting the consumer's account and crediting the merchant's account. Systems using notational money can support the concept of fiscal debt. Electronic payment orders over the Internet and credit-card billing over the Internet are the two most well known systems that use notational money.

Hybrid money combines the features of both token money and notational money. Automated clearinghouses and electronic checks form the major system using hybrid money. In the following, we discuss each of these systems in more details.

Electronic Bill Presentment and Payment Systems

These systems allow companies to bill customers for their services and in turn receive payments from them electronically over the Internet. There are two types of presentment models:

1. Direct model—A company (that is, a seller of a service) delivers the bill to customers (buyers of services) via either the company's own site (seller-direct model) or the customer's site (buyer-direct model).
2. Consolidator model—Bills from multiple issuers are delivered to a single site to be presented later in aggregate to the consumer for payment. A consolidator acts as an intermediary, collecting or aggregating invoices from multiple sellers for multiple consumers. Consolidators are generally third parties who may additionally provide a variety of financial services such as escrow, insurance, credit ratings, etc.

The following steps are involved in a system based on the direct model.

1. Enrollment—For the seller-direct model, the consumer enrolls in the company's bill-processing system using a standard Web interface. For the buyer-direct model, the seller enrolls in the customer's Web site that has been set up for this purpose. The site at which bill information is exchanged is henceforth called the bill processor.
2. Presentment—This occurs in the following steps:
 - a. The seller generates and/or transfers the invoice information to the bill processor.
 - b. The consumer is informed that a bill is ready.
 - c. The consumer accesses the bill-processing site to review and analyze the invoice information.

3. Dispute handling—The consumer may dispute a bill. To do this, the consumer contacts the seller for review of the bill.
4. Payment—This occurs in the following steps:
 - a. The consumer authorizes either full or partial payment for the bill.
 - b. If it is the seller-direct model, then the seller's financial institution processes the payment transaction; otherwise, the buyer's financial institution processes the transaction.
 - c. The appropriate financial institution confirms payment execution—credit to account for seller-direct model and debit from account for buyer-direct model.
 - d. The respective financial institution reports payment return or rejection information.

The consolidator model is very similar to the direct models. The differences are as follows:

1. Enrollment—Both the seller and the buyer have to register at the consolidator's bill-processing system.
2. Presentment and dispute handling are done using the consolidator as the intermediary.
3. Payment—The following steps are performed:
 - a. The consolidator initiates the payment and reports the activity to the buyer and the seller.
 - b. The payment transaction is processed by either the buyer's or the seller's financial institution. Sometimes, the consolidator assumes the role of a financial institution.
 - c. The financial institutions confirm execution of the payment.
 - d. Payment return or rejection information may be reported to both buyer and seller by their respective financial institutions.

Electronic bill or invoice presentment and payment systems are gaining considerable popularity among both buyers and sellers. The major reason is that these are much faster and more efficient than traditional systems. The advantage of the consolidator model over the direct model is that in this model both the seller and the buyer reduce the number of bill-processing sites with which each has to interact. The disadvantage is that each may have to pay a fee to the consolidator to avail of its services.

Credit-Card-Based Systems

Credit cards are by far the most popular form of online payments for consumers. Credit cards are widely accepted by merchants around the world. They offer a number of benefits for both the consumer and the merchant. A consumer is protected by a grace period during which he or she can dispute a credit-card purchase. A merchant has a high degree of confidence that a credit card can be safely accepted from an unknown and not trusted purchaser. Using a credit card to pay for online purchases

is just as easy as using it for a conventional purchase from a store. Merchants who already accept credit cards in an offline store can accept them immediately for online payment because they already have a merchant credit-card account. Online purchases require an extra degree of security. This is because a credit-card holder is not present and cannot be identified as easily as he or she can be when standing at the cash register. Online credit-card services must somehow authenticate the purchaser as well as protect sensitive information as it is transmitted on the Internet.

A credit card, such as that offered by Visa or MasterCard, has a preset spending limit based on the user's credit limit; the credit limit is determined by the customer's credit history, income level, and total wealth. The limit ranges from a few hundred to several thousand dollars. The user uses these cards to purchase goods and services or obtain cash from participating financial institutions. The user is required to pay his or her debt during the payment period. He or she can pay off the entire credit balance or pay a minimum amount each billing period. Thus, the credit provided by a credit card is a revolving credit. Credit-card issuers, however, charge interest on any unpaid balance.

A purchase card, on the other hand, is a special-purpose credit card that provides a nonrevolving credit line to the bearer. Purchase cards are issued by employers to employees for the sole purpose of facilitating payment for purchases made by the employee on behalf of the employer.

A charge card, such as one from American Express, is similar to a credit card except that it does not carry a preset spending limit, and the entire amount charged to the card is due at the end of the billing period. Charge cards do not involve lines of credit and do not accumulate interest charges. The distinction between credit cards and charge cards is unimportant in the discussion of processing credit and charge cards for electronic payment; the collective term *credit card* is used here to refer to both types.

Payment using credit cards generally involves one or more financial institutions for the processing of payment information. For some credit-card systems, banks and other financial institutions serve as a broker between card users and the merchants accepting the cards. These types of arrangements are called closed-loop systems because no other institution (local bank, national bank, or other clearinghouse) is involved in the transaction. American Express and Discover are examples of closed-loop systems because there is exactly one franchise for each of those systems. Open-loop systems can involve three or more parties. Besides the customer's and the merchant's banks, a third party, called an "acquiring bank," is involved. The acquiring bank passes authorization requests from the merchant's bank to the customer's bank to obtain authorization for the credit purchase from the customer's bank. A response is sent back to the acquiring bank and on to the merchant. Similarly, the acquiring bank is responsible for contacting the merchant's bank and the many customers' banks to process sales drafts. The merchant's bank usually plays the role of the acquiring

bank. Systems using Visa or MasterCard are the most visible examples of open-loop systems because many banks issue both cards. Unlike American Express or Discover, neither Visa nor MasterCard issues cards directly to consumers. Member banks are responsible for handling all the details of establishing customer credit limits. For this discussion, we will assume that there are four players involved in a payment-card transaction: the customer who uses a credit card, the merchant that accepts a credit card toward a payment, the acquiring bank, and the issuing bank.

The following steps are involved in credit-card processing:

1. The customer provides the credit-card information to the merchant using a secure online communication channel. The communication channel needs to be previously established between the customer, and the merchant and needs to provide security services such as authentication, confidentiality, and integrity.
2. The merchant processes credit-card payments using software provided by the acquiring bank. The software enables the merchant to submit the credit-card information electronically to the acquiring bank. Usually the merchant submits this information via a dedicated communication channel.
3. The acquiring bank sends a request to the issuing bank authorizing payment for the particular charge incurred by the customer. This request is typically sent over a protected financial services network.
4. The issuing bank either approves or declines the charge. If the charge is approved, the issuing bank puts a hold on the customer's account for the funds needed to satisfy the current charge and forwards an approval code to the issuing bank. If it is declined the issuing bank is notified.
5. The issuing bank sends the transaction (either the approval code or the decline information) back to the merchant.
6. The merchant completes the payment transaction.

Credit cards have several features that make them an attractive and popular choice to both consumers and merchants in online and offline transactions. For merchants, credit cards provide fraud protection. When a merchant accepts credit cards for online payment, he or she can authenticate and authorize purchases using a credit-card-processing network. For consumers, credit cards are advantageous because various consumer credit protection acts limit the cardholder's liability to small amounts if a card is used fraudulently.

The biggest advantage of using credit cards is their worldwide acceptance. A user can pay for goods with credit cards anywhere in the world, and the currency conversion, if needed, is handled by the card issuer. For online transactions, credit cards are particularly advantageous. When a consumer reaches the electronic check-out, he or she enters the credit-card number and his or her shipping and billing information in the appropriate fields to complete the transaction. The consumer does

not need any special hardware or software to complete the transaction.

Credit cards have very few disadvantages, but they do have one when compared with cash. Credit-card service companies charge merchants per-transaction fees and monthly processing fees. For example, MasterCard charges \$0.29 plus 2 percent of the transaction value for each transaction. This is in addition to any fee that the acquiring bank may charge the merchant. Thus, credit-card transactions are quite expensive. However, online (and offline) merchants view them as a cost of doing business. Any merchant that does not accept credit cards for purchases is probably losing a significant number of sales because of it. In addition, credit cards typically provide a built-in safety net for merchants, as they have a higher degree of assurance that they will be paid through companies that issue credit cards. This makes credit cards generally lucrative to merchants for online payments. The consumer often does not pay any direct fees for using credit cards (there may be some fees, for example, when a credit card is used in a transaction in a foreign country requiring currency conversion), but the prices of goods and services are slightly higher than they would be in an environment altogether free of credit cards. A second disadvantage over cash is that obtaining a credit card is not trivial. The onus is on the consumer to demonstrate creditworthiness in order to get a credit card; thus, many may not qualify for credit cards, while anyone can get and use cash.

Debit-Card-Based Systems

Debit cards are another form of electronic payment system that falls somewhere between credit cards and personal checks. Though they look very much like credit cards, they operate differently. Unlike credit cards, which make funds available through a financial institution, debit cards are a way to pay now and to subtract money automatically from the cardholder's bank account. There are two types of debit cards—PIN-based or online debit cards, and signature-based or offline debit cards. They differ in the ways debit payments are processed.

PIN-based debit transactions are fast, convenient, and secure. It calls for customers to endorse payments by submitting a personal identification number (PIN) at the point of sale. The transaction is authorized in real time. Funds in the customer's account are set aside immediately to pay for the transaction. The money is transferred into the merchant's account in 2 to 3 business days. Merchants pay a nominal transaction fee, much lower than a typical credit-card transaction. The fact that customers authorize charges with PINs that are known only to them virtually eliminates the risk to merchants of charge backs. However, this type of debit transaction is currently available only in the physical world. This is because customers need access to a physical, discrete PIN-entry device (the PIN pad) that has to be integrated with the payment system. A number of financial institutions are introducing technologies that attempt to mimic the functionality of PIN pads. However, widely accepted operating standards have yet to be established.

Signature-based debit cards do not involve PINs. These are typically offered by credit-card companies, and

may be used everywhere that credit cards are accepted. Merchants complete the debit sale in much the same way as credit sales. The transaction is processed through a credit-card-processing network for authorization. The customer signs the sales draft that authorizes the merchants to charge the customers' accounts. Transactions normally settle in 2 to 3 business days. Because these transactions are processed through the same networks as credit cards, they often incur the same transaction fees for the merchant.

Electronic Funds Transfer

The discussion of electronic payment systems would be incomplete without discussing electronic funds transfer (EFT) systems. An EFT transaction provides for electronic payment and collection. It is transfer of funds initiated through an electronic terminal, electronic mail, telephone, computer, or magnetic tape. It is comprised of the generation and delivery of instructions that directs a financial institution to either credit or debit a consumer's asset account. The term *EFT* itself does not refer to a specific product. Rather, it is a descriptor that defines payment vehicles that use electronic networks to conduct a transaction. Historically, the core of consumer EFT networks has been the automated teller machine and associated access cards. Currently, an EFT transaction involves payment processing through one or more of the electronic payment systems discussed earlier. The following are the most common EFT systems.

1. *Automated Teller Machines, or 24-Hour Tellers.* These electronic terminals let a customer perform banking at almost any time. Services offered through these computer systems, though limited, are quite comprehensive. Customers can withdraw cash, make deposits, query account balances, or transfer funds between accounts at the same bank. The customer initiates the transaction by inserting an ATM card and entering a PIN. The ATM card is encoded with the customer's account information on a magnetic strip. This information is transmitted to the bank's central computer by modem over either a dedicated telephone line or a normal dial-up telephone line. The information is protected via encryption during transmission. After proper authentication, the bank's central computer allows the ATM to complete the transaction. Banks have formed global networks so that a customer of one bank can use an ATM of another. Often ATM networks are also connected to credit-card and debit-card-processing networks. In these cases, the ATM machine allows a customer to use a credit or debit card; however, the customer is limited to withdrawing cash. Such transactions are processed as typical credit-card or debit-card transactions.
2. *Direct Deposit.* This lets the customer authorize specific deposits such as paychecks, stock dividends, and pensions to the customer's bank account either on a regular basis or on an ad hoc basis. It also allows the customer to preauthorize direct withdrawals so that recurring bills such as insurance premiums, mortgages, and utility bills are paid automatically. By completing

a standard enrollment form, a customer authorizes a company or organization to make a credit payment to or a debit payment from one or more of his or her accounts. The actual transaction is then processed over the automated clearinghouse (ACH) system as an ACH transaction.

3. *Pay-by-Phone Systems.* These systems let a customer call his or her financial institution with instructions to pay certain bills or to transfer funds between accounts. The customer must have a previous agreement with the bank for such transactions. Usually these transactions are limited to within the customer's own bank—that is, the customer cannot use a pay-by-phone system to transfer money between accounts at different banks. For services such as bill-pay, the bank uses a system such as ACH to complete the transaction. To use pay-by-phone, the customer dials a special phone number on a touch-tone phone to access the central computer of the bank. After proper authentication of the customer, usually through a PIN, the computer allows the customer to proceed with the rest of the transaction. Pay-by-phone systems typically offer a limited number of services. Moreover, these systems are not very secure. This is because of the inherent vulnerability of the public telephone network. The popularity of these systems is gradually waning and being replaced by personal computer banking.
4. *Personal Computer Banking.* This allows the customer to handle many banking transactions over the Internet via a remote computer. The system works very much like the pay-by-phone system. The customer uses a computer to connect to the central computer of his or her bank. After proper authentication, the customer is allowed to view account balances, request transfers between accounts, and pay bills electronically. Bill payment is processed offline as ACH transactions. The ability to use strong cryptographic techniques makes these systems more secure than pay-by-phone systems.
5. *E-Mail-Based Person-to-Person Payment.* This allows the customer to send a one-time payment instruction to a financial institution using e-mail. The financial institution authenticates the payment instruction by presenting some kind of a challenge to the payer. Once the challenge has been responded to in an appropriate manner, the financial institution credits the payee's account with the appropriate amount.
6. *Electronic Check Conversion.* This system converts a paper check into an electronic payment at the point of sale or elsewhere, such as when a company receives the customer's check in the mail. Electronic check conversion links two existing technologies—a magnetic ink character recognition (MICR) scanner and the ACH network. The paper check is processed through a MICR scanner to capture the check number, the number that identifies the customer's bank, and the customer's account number. The information is used to make a one-time electronic payment from the customer's account. The check itself is not the method of payment. This means that the cancelled check is not returned to the customer with his or her account statement.

Electronic Cash

Electronic cash (or e-cash) (Weber 1998) is a method of payment in which a unique number or identifier is associated with a given amount of money at a financial institution. It is often suggested as an alternative method to credit cards for purchases made over the Internet. Some definitions of electronic cash are much broader, describing it as any form of "prepaid, stored value that can be used for electronic purchases" (van Slyke and Belanger 2002). However, these systems are better categorized as electronic purse systems. The use of electronic cash requires the customer to open an account in a bank and then deposit money to this account. The bank provides the customer with a unique digital coin (essentially a unique identifier) that is used for all electronic payments.

Any electronic cash system needs to possess five characteristics if it is to be usable and universally accepted. First, it must be ensured that the electronic cash is spendable only once; that is, double spending should be prevented at all costs. This is needed to ensure that both parties involved in the transaction knows that the e-cash currency being received is not counterfeit or being used in two different transactions. Second, the e-cash system has to be independent of any particular proprietary storage or transmission mechanism. Third, electronic cash must be portable; it should be able to pass transparently across international borders and be automatically convertible to the recipient country's currency in all forms of peer-to-peer transactions. Fourth, electronic cash must be divisible. Divisibility determines the size of payment units. Both the number of different electronic cash units and their values can be defined independently of real currency. The denominations are up to the definers and are not limited to the typical breakdowns of a traditional cash system. Finally, e-cash systems should be anonymous, very much like their paper-world counterpart. The consumer (and sometimes the seller) should be able to use e-cash without revealing her or his identity. However, as explained later, ensuring the last property also makes the prevention of double spending rather difficult.

Double spending is extremely difficult to detect and/or prevent with truly anonymous electronic cash. Anonymous electronic cash is electronic cash that, like bills and coins, cannot be traced back to the person who spent it. To ensure anonymity or unlinkability of the customer, the payment protocol cannot associate any form of customer's identification mark with the cash system—much in the same way as in traditional cash systems. This implies that the bit string that represents electronic cash is not traceable to the customer who spends it. Since it is rather trivial to make multiple copies of the bit string representing cash, anybody can make counterfeit electronic cash, without fear of being caught and prosecuted. One way to be able to trace electronic cash (to prevent money laundering) is to attach a serial number to each electronic cash transaction. That way, cash can be positively associated with a particular consumer. This does not, however, solve the double spending problem completely. While a single issuing bank can detect whether two deposits of the same electronic cash are about to occur, it is impossible to ascertain who is at fault—the consumer or the

merchant. If the duplicate electronic coins are presented to two different banks, the problem is exacerbated. Further, it is not easy to develop an electronic cash system in which the cash can be traced back to its origin. Complex cryptographic algorithms are needed to create tamperproof electronic cash that can also be traced back. Electronic cash containing serial numbers also raises a number of privacy issues, because merchants could use the serial number to track spending habits of consumers. The whole purpose of electronic cash systems—namely the ability of a customer to remain anonymous—is lost. It is important that a procedure is available both to protect the anonymity of electronic cash users and to provide built-in safeguards to prevent double spending.

One advantage of electronic cash is that like real cash it tends to be less costly to both merchants and consumers. This can make micropayments (where the value of the payment is comparable to or even less than the cost of the transaction) using electronic cash feasible. Micropayment fundamentally creates a new billing model, under which the individual items purchased can be billed separately and individually. With micropayment methods, consumers can download a song or a chapter of a book and be billed as little as 50 cents or a dollar, with that small amount being charged to their Internet service provider (ISP) or phone bill. Security issues with micropayments are primarily centered on the premise that a small charge would not require extensive use of encryption technology or other means of fraud prevention. The widespread use of micropayments is a potential breeding ground for fraud that today is not apparent. The lack of an authoritative infrastructure standard, coupled with strong network externalities, has limited micropayments from becoming a dominant means of value transfer.

Micropayment

Micropayment is a new model of electronic payment for goods or services in situations in which the cost to transact the payment by conventional means, such as credit cards or electronic checks, far exceeds the value of the actual payment. To make payments in a cost-effective manner, micropayment systems gather a large number of small payments intended for a specific merchant and batch process them for financial institutions as one single transaction. Micropayment systems are designed to support large numbers of small payments with the help of an intermediary broker. The broker acts on behalf of the merchant (maybe several merchants) to collect payment. Micropayment protocols can afford to have lesser security features for individual payments. This is because the amount of money lost on a single payment is considered within the range of tolerable risks.

Electronic Purse or Stored-Value Card

An electronic purse, as defined by the United Kingdom Banking Code, is “any card or function of a card which contains real value in the form of electronic money which someone has paid for in advance, and which can be reloaded with further funds and which can be used

for a range of purposes.” These are essentially prepaid stored-value cards. As with electronic cash systems, the consumer needs to deposit real money with the issuer of the purse. The amount of money deposited is then encoded into the card. As purchases are made using the electronic purse, the value in the card is reduced and the amount is credited to the merchant’s account. The development of electronic purses has been driven almost wholly by commercial and technological organizations rather than by demand from consumers. The organizations operating electronic purse systems gain from the use of the money stored on the cards. For banks, there are advantages in reducing the handling of cash and checks, which have to be transported securely and are labor-intensive to handle. For the retailer, the advantages are the reduction in handling of currency and checks. This includes reducing the delay in money being credited to the retailer’s bank account. Another advantage is reducing the risk of theft.

A stored-value card can be as elaborate as a smart card or as simple as a plastic card with a magnetic strip. One of the most common stored-value cards is a prepaid phone, copy, subway, or bus card. These cards can be recharged with more value by inserting them into special machines, inserting currency into the machine, and withdrawing the card. Another example is the retail store “gift card.” These cards can be purchased at retailers for a fixed denomination. Most of the time, they cannot be recharged. Unlike smart cards, magnetic strip cards are passive. That is, they cannot send information such as a customer’s digital certificate, nor can they receive and automatically increment or decrement the value of cash stored on the card. Smart cards evolved from magnetic strip cards. Instead of encoding and storing data using a magnetic strip, a computer microchip is embedded on the card itself, containing information about the owner, such as financial facts, private encryption keys, account information, credit card numbers, and so on. Like magnetic-strip cards, smart cards can be used online and offline. Smart cards are better suited for Internet payment transactions because they have more processing capability than the magnetic stripe cards.

Electronic purses have gradually become one of the most widely used electronic payment systems for consumers. The advantages include ease of use, ability to pay the exact amount without searching for change, no authorization requirement, and the possibility of depositing additional value as and when required. However, a major disadvantage from the consumer’s point of view is that the purse is as good as real money. If it is lost or stolen, the consumer loses. To protect against such losses, smart-card technology is now being more widely used that allows units of credit to be reloaded. Another disadvantage, especially with retail store gift cards, is that they often come with expiration dates. If the card is not used within this period, the money is lost to the consumer. This provides a significant benefit to the issuer, however. A final shortcoming is that seldom is the card completely spent in one transaction. If the card is not rechargeable and the balance left in the card is not sufficient for another transaction, then the balance is, more or less, money lost to the consumer.

Electronic Wallets

Today's online shoppers have begun to tire of repeatedly entering details about shipping and payment information each time they make an online purchase. Research has shown that filling out forms rank high on online customers' lists of grievances about online shopping. Electronic wallet technology is intended to solve this problem. At the same time, an electronic wallet provides a secure storage place for credit-card data and electronic cash. In short, an electronic wallet (or e-wallet), serves a function similar to a physical wallet; it holds credit cards, electronic cash, owner identification, and owner contact information and provides that information at an electronic commerce site's checkout counter. Occasionally, an e-wallet may contain an address book. Some wallets also hold an encrypted digital certificate, which securely identifies the wallet's owner. E-wallets make shopping more efficient. An e-wallet simplifies the online checkout process. A simple click inserts the e-wallet information into the payment forms on the merchant's site. E-wallets can also provide many additional services. They can keep track of the owner's purchases by saving receipts. An enhanced digital wallet can even suggest where a consumer may find the best price on an item that he or she purchases on a regular basis.

E-wallets are of two types based on where they are stored. A client-side e-wallet stores a consumer's information on the consumer's own computer. This shifts the responsibility for ensuring the e-wallet's security to the end user. This can be regarded as both an advantage as well as a disadvantage. It is an advantage because the user has more control in keeping the e-wallet secure; it is a disadvantage because users may not always take appropriate measures. Many of early e-wallets were client-side wallets and required lengthy downloads, which was one of their chief disadvantages. Another disadvantage of client-side e-wallets is that they are not portable. They are not available when the owner is making a purchase at a location other than the computer on which the wallet resides. A server-side electronic wallet alleviates this problem; it stores a customer's information on a remote server belonging to a particular merchant or belonging to

the wallet's publisher. The main weakness of server-side e-wallet is that a server-side security breach could reveal personal information for thousands of users. Server-side e-wallet systems typically use strong security measures that minimize or eliminate the possibility of unauthorized disclosure.

For a wallet to be useful at many online sites, it should be able to populate the data fields in any merchant's form at any site that the customer visits. This accessibility means that the e-wallet manufacturer and merchants from many sites must coordinate their efforts so that a wallet can recognize what consumer information goes into each of a given merchant's forms.

Electronic Checks

Electronic checks are a comparatively new and still emerging technology that combines high security, speed, convenience, and processing efficiencies for online transactions. They are based on the premise that electronic documents can be substituted for paper and public-key-cryptography-based digital signatures can replace handwritten signatures. Thus, the attraction is that electronic checks can replace paper checks without the need to create a new payment instrument, together with the implied legal, regulatory, and commercial practice changes. The technology promises several advantages. It leverages the time-tested paper-based check payment system and uses the same legal and business protocols. It works like a paper check but in a pure electronic form, with all the associated efficiency. It can be used by all bank customers who have check-signing privileges. Last but not least, it includes enhanced security features that allow automatic verification of content and validity, thereby helping to reduce check fraud.

Electronic checks work the same way as a traditional paper check does (see Figure 1.). The steps involved in electronic check processing can be summarized as follows:

1. The payer retrieves an "electronic check" from an "electronic checkbook" and electronically fills in the check just as he or she would fill in a paper check.

Figure 1: Steps involved in payment using electronic checks

2. The payer digitally signs the check and includes any necessary certificates with the check.
3. The payer then gives the electronic check to the payee using one of several secure electronic means (e.g., through secure e-mail or over secure Web connections).
4. The payee endorses the electronic check by putting its digital signature on the check.
5. The payee then electronically deposits the endorsed check in the payee's bank and receives credit.
6. The payee's bank submits (also electronically) the electronic check to the paying bank for clearing.
7. The paying bank validates the electronic check and then charges the payer's account for the check.

Mobile Payment System

With the rapid growth of wireless technologies (see Volume II, Part 3—Cellular and Wireless Networks) the financial industry is increasingly aiming toward providing mobile financial services to the end user. The vision is that the mobile communications channels will be used in financial transactions not only to complement communications over wired channels but also to usher in newer services that only mobility can enable. For example, stock alerts can be sent to wireless personal digital assistants (PDAs) so that the active trader can conduct transactions while on the move, independent of space and time constraints. Or, for example, the user can use a cellular phone for buying snacks from a vending machine. The rationale for such a vision is that mobile devices like cellular phones, wireless-enabled PDAs, and so on will increasingly become the platform of choice for users for managing their finances (e.g., accessing their bank accounts or investing in the stock market), making purchases in local environments (e.g., within a store) and remote environments (e.g., over the Internet), and securing authenticated access to various services.

Mobility can be accorded to electronic payment systems in one of three ways: (1) using wireless communication technology as a substitute for standard wired communication channels, and (2) using the new paradigm of contact-less payment. The first method is used mostly for traditional financial transactions like purchasing over the Internet. Broadband wireless access (see the chapter "Wireless Broadband Access") is typically used to support wireless access to data networks when this method is used from mobile laptops. When network access is desired using slower carrier-based mobile communication technology like global system for mobile (GSM) or code division multiple access (CDMA) communications as in PDAs or cellular phones, a still evolving standard called WAP (wireless application protocol—see the chapter "Wireless Application Protocol (WAP)") is used to support these applications. There are no major changes to the underlying payment protocols, and hence this method will not be discussed further in this section. The second method, on the other hand, is a relatively newer model of noncash electronic payment

that has been enabled by emerging technologies such as Bluetooth (see the chapter "Bluetooth Technology") and wireless infrared communication (see the chapter "Indoor Wireless Infrared Communications"). The major characteristic of these technologies is the relative short communication range offered (typically in the range of a few centimeters for radio-frequency devices to tens of meters for Bluetooth-enabled devices). Thus, the second method finds widest adoption at retail point-of-sale terminals. Sometimes this method of payment is complemented by carrier-based mobile technologies such as CDMA and GSM.

Contact-less payment is based on establishing a wireless communication between a user's payment device that stores one of the forms of electronic money discussed earlier and a point-of-sale payment terminal or infrastructure device. The technology can be broadly classified into five major categories depending on the wireless communication method used—radio waves or infrared light. These are:

1. ISO 14443 proximity card standard-based methods
2. ISO 15693 vicinity card standard-based protocols
3. Proprietary radio-frequency technology-based protocols
4. Bluetooth-based systems
5. Payment systems by cellular service providers
6. Infrared communication based protocols

The first three use radio waves at different frequency levels for communication. The fourth and fifth technologies use microwaves, and the last uses line-of-sight infrared beams for communication.

ISO 14443–Based Proximity Devices

The ISO 14443 specifications provide the standard for contact-less smart cards that usually use the standard credit-card form defined by ISO 7810 ID-1. However, other forms are also used, such as watches and mobile phones. These devices use either low-frequency radio waves in the 125-KHz band (rare) or high-frequency radio waves in the 13.56-MHz band (most common) with a transmission speed in the range of 106 to 424 Kbps. The fast transmission speed allows the devices to be present in the proximity for a very short while for the transaction to be completed. The operational range of these devices is on the order of tens of centimeters. This means that the customer's payment device has to be in close proximity to the point-of-sale payment terminal. Thus, the customer cannot repudiate an intention to pay at a later time. In addition, although radio-wave communication is a broadcast technology in the sense that anyone with a suitable receiver can eavesdrop on the communication, the close proximity of the two devices helps limit unintended communication significantly. Broadcasting brings with it one more challenge—that of collisions. If more than one such device is placed within the communication field at the same time, there may be collisions among the packets transmitted between

the different devices. ISO 14443 specifies how such collisions are handled.

Typically, these proximity devices are used as stored-value cards. They are widely used in automatic fare collection for mass-transit systems and offline purchases in vending machines. In recent years, smart cards have been provided with built-in microprocessors. These smart cards provide strong cryptographic protection of the communication channels and thus enable all the functionalities of contact smart cards. A number of credit-card providers, including Visa and MasterCard, are offering such ISO 14443-based smart cards that are also equipped with conventional magnetic stripes. These cards allow all the features of the conventional credit and debit cards from these groups in a contact-less manner.

ISO 15693–Based Vicinity Devices

The ISO 15693 specifications provide the standard for contact-less “vicinity cards.” These devices come in various forms, such as key fobs, car tags, and plastic cards. Typically, these operate in the 13.56-MHz high-frequency range, like the ISO 14443 devices. However, they have a much slower transmission rate—typically around 20 Kbps. Thus, the devices need to be in the vicinity of the communicating device for a longer period for the transaction to be completed. The operation range of these devices is between 1 and 1.5 m. Although this can be a benefit for a number of applications, like parking and vending, it also brings in added security risks. Unlike ISO 14443 devices, ISO 15693 devices do not convey any payment intention on the part of the user. Thus, a user can repudiate a payment with the claim that a malicious attacker with a similar device had been in the vicinity and falsely made the charge. The possibility of eavesdropping increases for these devices, as does the possibility of unintended communications. This requires additional security measures to be incorporated within the devices. These devices broadcast the transmission like ISO 14443 devices. The ISO 15693 specifications address the problem of collisions during communication.

Vicinity devices find major application as electronic debit cards in closed systems like toll collection, gas pumps, and vending machines.

Proprietary Radio-Frequency Technology Systems

There have been attempts to develop proprietary contact-less payment devices for use in various closed systems. These use radio waves at different frequency bands: 100–300 KHz, 13.56 MHz, and 900–928 MHz. The operating ranges of these devices vary significantly. For example, the devices in the 13.56-MHz frequency range operate as proximity devices, while those operating in the ultra-high-frequency range (900+ MHz) provide an operating range of several meters. All the problems of the ISO 14443- and ISO 15693-compatible devices are also observed among these devices, and similar solutions have been proposed. Because of a lack of standardization, these devices have yet to find widespread usage.

Bluetooth-Based Systems

Bluetooth is a wireless technology that can be used to interconnect devices such as PDAs, laptops, digital cameras, mobile phones, etc. using a secure globally unlicensed short-range radio frequency. Bluetooth-enabled devices come in various power ranges (from 1 to 100 mW) that provide them with operating ranges of up to 100 m. There have been some attempts to develop payment applications based on Bluetooth. However, two major technical challenges impede the wide adoption of this technology for payment. First, Bluetooth does not provide a wide enough operating range to be used as an alternative to cellular services. They are primarily intended to facilitate IEEE 802.15-based personal area networks. This signifies that they can be used only for vicinity payment systems. In this context also, Bluetooth suffers because it does not offer any point-to-point localization, which is the second technical challenge.

Payment System by Mobile Carriers

The rapid growth of high-speed data networks, like 2.5 and 3G, has opened up the possibility of carrier-based mobile devices being used for electronic payment. A number of mobile service providers have teamed up with the financial services industry to form the Mobile Payment Forum (www.mobilepaymentforum.org), which is “dedicated to realizing the full potential of mobile commerce.” Various technologies have been proposed, including using short/medium message service (SMS/MMS) messages for payment authorization and integrating mobile phones with ISO 14443/ISO 15693/proprietary radio-frequency devices. There is a continuing active interest in this area. However, as of today no significant system exists that provides contact-less payment using a carrier-based system. Lack of interoperability and the high total cost of ownership are often cited as the primary reasons why these systems have not become popular.

Infrared Communications–Based Protocols

The Infrared channel is one of the oldest wireless communication technologies. It provides a line-of-sight communication protocol—that is, the two communicating devices need to have an unobstructed view of each other in order to communicate. Infrared devices can theoretically communicate over several meters; however, an operational range of 20 to 30 cm is more practical and consumes very little power. Thus, infrared-enabled devices such as PDAs and mobile phones offer opportunities to be used as electronic “vicinity” payment devices. A number of projects have looked into maintaining mobile wallets in these devices. Customers can beam payment information from these wallets to point-of-sales terminals at physical retailers. A major advantage of infrared wireless communication is that the line-of-sight property provides some degree of protection from eavesdropping, although application-level security in terms of encryption and authentication must still be provided for protecting the payment information from other types of attacks. Lack of interoperability standards among various infrared-enabled devices is the major hurdle in the wide adoption of this technology.

REPRESENTATIVE TECHNOLOGIES

Electronic Bill Presentment and Payment Systems

CheckFree

CheckFree (www.checkfree.com) is the largest online bill processor. It provides online-payment-processing services to both large corporations and individual Internet users. CheckFree Corporation provides a wide range of electronic commerce solutions, including online share portfolio management in conjunction with the PAWWS system (www.pawws.com) and general online bill payment systems. CheckFree provides the infrastructure and software to permit users to pay all their bills with online electronic checks. It offers an electronic check payment service as a replacement for traditional paper checks. This payment system results in a service similar to money orders. Their software is compatible with the wallet software from Cybercash. For bill processing, the customer receives a bill from a service provider and sends the payment information to CheckFree. The customer creates an account with CheckFree that is linked by direct debit to the customer's bank account. CheckFree pays the bill on the customer's behalf in the form of electronic checks. If required, CheckFree can also pay the bill in the form of a traditional paper check.

Electronic Wallet Systems

Many electronic wallet systems are commercially available for pocket, palm-sized, handheld, and desktop PCs. The current technology trend is to produce electronic wallets in the smart card. In the electronic payment system developed in the CAFE (Conditional Access For Europe) project, the electronic wallet can be either in the form of a small portable computer with an internal power source or in the form of a smart card. Electronic money can be loaded into the wallets online and used for payments at point-of-sale (POS) terminals. Examples of e-wallet applications include Microsoft's Passport (Microsoft Corporation 2004) (the system is used mainly as a form of single-sign-on framework rather than as an electronic payment system), Ilium Software's eWallet (Ilium Software 2004), VeriFone's Vwallet (www.verifone.com—now integrated into its Integrated Payment Solutions payment software), and Qwallet.com's Q*Wallet (Qwallet.com 2004). Numerous banks and companies have now developed their own e-wallets, such as AT&T's e-wallet or MasterCard's e-wallet.

Credit-Card-Based Systems

Secure Electronic Transaction (SET) Protocol

Secure electronic transaction, or SET, is a secure protocol jointly developed in 1996 by MasterCard and Visa with the backing of Microsoft, Netscape, IBM, GTE, SAIC, and other companies, to facilitate credit-card transactions over the Internet (Schneider 2006). SET specifications were published in 1997 as an open standard, which allows all companies developing related applications to use this protocol and make their products work together successfully.

The objective of SET is to provide security for credit-card payments as they traverse the Internet from the

customer to the merchant sites and on to the processing banks. SET has been developed to secure the entire credit-card-payment process, including verifying that the consumer is indeed the owner of the credit card. While Visa and MasterCard have publicly stated that the goal of proposing the SET protocol is to establish a single method for consumers and merchants to conduct payment-card transactions on the Internet, acceptance of the standard has been slow. SET Co. is the consortium that manages and promotes the SET standard. The SET protocol assumes an already established public key infrastructure. The SET specification uses public key cryptography and digital certificates for validating all participants in the transaction. In contrast to the secure sockets layer (SSL) protocol, which provides only confidentiality and integrity of credit-card information while in transit, the SET protocol provides confidentiality of information, payment data integrity, user and merchant authentication, consumer nonrepudiation, and payment clearinghouses (certificates).

The major components of SET are as follows:

1. The issuer (or customer's bank) is a financial institution that issues bankcards (credit cards or debit cards).
2. The customer (or cardholder) is an authorized user of the bank card, who is registered with SET. The customer participates in the SET transaction by using an electronic wallet. SET calls this the "cardholder wallet." This is where the customer/consumer's credit-card information is stored in an encrypted manner. The wallet software is able to communicate and interoperate with other SET components.
3. The merchant is the seller of goods and services. The merchant uses the merchant server software to automatically process credit-card authorizations and payments.
4. The payment gateway processes merchant authorization requests and payment messages, including payment instructions from cardholders. It is operated by either an acquirer or some other party that supports acquirers (for example, the merchant's bank). It interfaces with financial networks to support the capture of SET transactions.
5. One or more certification authorities issue and verify digital certificates related to public keys of customers, merchants, and/or the acquirers or their gateways. The SET public key infrastructure proposes a top-down hierarchy of certification authorities comprising the following types:

- *Root certification authority:* All certification paths start with this authority's public key. It is operated by an organization that the entire industry agrees to trust. The initial root-key is built in to the SET software with a provision for replacing it in the future. It issues certificates to brand certification authorities.
- *Brand certification authority:* These authorities are operated by different credit-card brand owners like Visa and MasterCard. Each brand has considerable autonomy as to how it manages the certificate subtree rooted at it.

- *Geopolitical certification authority*: This is an optional level of certification authority. It allows a brand to distribute responsibility for managing lower-level certificates across different geographic or political regions. This is to account for variations in how financial systems operate in different regions.
- *Cardholder certification authority*: These authorities generate and distribute cardholder certificates to cardholders. Depending on brand rules, the certification authority may be operated by an issuer or another party.
- *Merchant certification authority*: These authorities issue certificates to merchants based on approval by an acquirer.

The SET infrastructure is deliberately planned not to interoperate with any payment infrastructure other than the bank-card system. Although this may be considered a restriction of SET, it ensures that the operating organizations are not subjected to any unknown risks. The main steps of SET are described in the Figure 2. The sequence can be summarized as follows:

1. *Customer and merchant registration*: In this step (messages labeled 0 in Figure 2), the customer and the merchant acquire relevant certificates from the corresponding authorities that will allow them to participate in the transaction. This needs to be done once before any SET transaction and needs to be reexecuted if the certificates expire or are revoked.
2. *Browse and negotiate purchase*: This step (message 1) proceeds separately from the main protocol; it allows the customer to select the product and negotiate on a price. SET is not involved in this phase.

3. *Purchase request*: Once the customer has completed the product selection process, it invokes the cardholder wallet software on its machine. This is where the main SET protocol starts (message 2). The cardholder wallet initiates a SET session with the merchant server; it sends its certificate to the merchant and requests a copy of the merchant's certificate and the payment gateway's certificate. On receipt of these, the cardholder wallet creates payment information (PI) and order information (OI). The PI includes the cardholder's credit-card account information and public key certificate, among others. The OI includes necessary information about the order. Two digests are computed, one each for PI and OI. They are concatenated and signed by the customer's private key. The PI is encrypted with payment gateway's public key. Next, the OI and encrypted PI are together encrypted with the merchant's public key. Finally, the entire message is signed and sent to the merchant server. The merchant server verifies the cardholder's certificate. It verifies the signature on the PI and OI. If it agrees to the OI, it forwards the encrypted PI to the payment gateway (PG) for authorization (message 3). While waiting for authorization, the merchant prepares an order confirmation (OC), signs it with its private key, and sends it encrypted with the customer's public key.
4. *Payment authorization*: To request payment authorization, the merchant sends the encrypted PI (received in step 3) signed with its private key (message 3) to the payment gateway. The payment gateway verifies the merchant's signature on the message, decrypts the PI with its private key, and retrieves the customer's certificate. It then verifies the relevant signature, and performs an authorization at the issuer (message 4).

Figure 2 : Steps involved in a SET transaction

When the issuer authorizes payment (message 5), the payment gateway generates an authorization response (AR) and a capture token (CT). Both are signed by the payment gateway's private key and sent to merchant encrypted with the latter's public key. The merchant, on receipt, stores the payment authorization response and capture token for later use.

5. *Payment capture:* The merchant prepares a payment capture request with the transaction identifier from the original OI and the CT obtained earlier. It signs the capture request (CR) and sends it encrypted with the PG's public key (message 7). The payment gateway verifies the CR message and sends a clearing request (CLR) message to the issuer (message 8). When the issuer clears the payment (message 9), the payment gateway generates a CR and sends it encrypted with the merchant's public key. The merchant stores the CR and completes the transaction with customer.

A major advantage of using SET for electronic credit card payment over using the SSL protocol to do the same is that SET does not allow the merchant to view the customer's credit-card information. This provides an additional degree of protection to credit-card information. This is unlike SSL, in which the merchant has the complete credit-card information. In addition, SET prevents the payment gateway and/or the issuer bank from being able to view the terms of the transaction established between the merchant and the customer. This way the privacy of the customer is also enhanced. However, SET has received a lukewarm reception in the United States and, so far, has not attracted a large number of merchants and consumers, though it seems to be the "best" protocol for securing payment over the otherwise unsecured Internet. The major SET activities are in Asian and European nations. Part of the problem with the acceptance of SET is that apparently, it is not as easy to implement or as inexpensive as most banks and merchants had expected. The typical reaction of many banks to SET is that it is clumsy—not tried and tested. The future might prove brighter for SET, though. After a few years of testing and trials, SET's supporters believe it is ready for widespread deployment.

Electronic Funds Transfer Systems

Automated Clearinghouse

The automated clearinghouse (ACH) system was developed in the United States in the 1970s by the banking industry in an effort to allow automatic funds transfer by replacing the paper check. The ACH system supports both debit and credit transactions. ACH payments include direct deposit of payroll and social security and other government benefits tax refunds; direct payment of consumer bills such as mortgages, loans, utility bills, and insurance premiums; business-to-business payments; E-checks; and e-commerce payments.

The ACH system is a batch processing store-and-forward system. Transactions received by the financial institution during the day are stored and processed later in batch mode. ACH transactions are accumulated and sorted by destination for transmission. Typically, five participants are involved in an ACH transaction (see Figure 3). (1) The originating company or individual (Originator) initiates a fund transfer from its account. (2) The Originating Depository Financial Institution (ODFI) receives a payment instruction from an originator and forwards it to the ACH Operator. (3) The Receiving Depository Financial Institution (RDFI) receives ACH entries from the ACH operator and posts the entries to the accounts of receivers. (4) The receiving company, employee, or customer (Receiver) authorizes an originator to initiate an ACH entry to the receiver's account with the RDFI. (5) The ACH Operator is the central clearing facility to or from which participating depository financial institutions transmit or receive ACH entries.

PayPal

PayPal (eBay Inc. 2002) operates very differently from ACH. It originally began as a payment system for person-to-person (P2P) payments via e-mail. Of late, it has become a very popular method for consumers to pay for online purchases. Owned by eBay Inc. and touted as the world's first e-mail payment service, PayPal.com is a free service that earns a profit on the float, which is money that is deposited in PayPal accounts. PayPal is very popular with eBay auction customers—it is currently the

Figure 3: Steps involved in an ACH transaction (Courtesy of NACHA—The Electronic Payments Association [www.nacha.org/what_is_ach.html])

number one electronic cash system used by eBay. PayPal eliminates the need to pay for online purchases by writing and mailing checks or using credit cards. PayPal allows consumers to send money instantly and securely to anyone with an e-mail address, including an online merchant. PayPal is a convenient way for auction bidders to pay for their purchases, and sellers like it because it eliminates the risks of accepting other types of online payments. PayPal transactions clear instantly so that the sender's account is reduced and the receiver's account is credited when the transaction occurs. Anyone with a PayPal account—online merchants and eBay auction participants alike—can withdraw cash from their PayPal accounts at any time.

To use PayPal, merchants and consumers first must register for a PayPal account. There is no minimum amount that a PayPal account must contain. Customers add money to their PayPal accounts by sending a check or using a credit card. Once members' payments are approved and deposited into their PayPal accounts, they can use their PayPal money to pay for purchases. Merchants must have PayPal accounts to accept PayPal payments, but consumer-to-consumer markets such as eBay are more flexible. Using PayPal to pay for auction purchases is very popular. A consumer can use PayPal to pay a seller for purchases even if the seller does not have a PayPal account. When one uses PayPal to pay for purchases from a seller or merchant who does not have a PayPal account, the PayPal service sends the seller or merchant an e-mail message indicating that a payment is waiting at the PayPal Web site. To collect PayPal cash, the seller or merchant who received the e-mail message must register and provide PayPal with payment instructions.

ELECTRONIC CASH SYSTEMS

CAFE

The European Union project CAFE (Conditional Access For Europe) (European Community's ESPRIT Program 1995) is an offline direct cash-like scheme that guarantees customer anonymity. The CAFE project ended in mid-1997, but has been continued in the follow-up project, OPERA. The partners in OPERA—that is, banks that support CAFE—are continuing the trial of and improving the CAFE system. About thirteen partners from several European countries were involved in the project, DigiCash² and Siemens among them. The system is designed for use in shops rather than over the Internet. In a way, it is the offline, portable versions of the DigiCash ECash system. It is based on the system proposed by Brand's cash. The protocol is disclosed for public review. An important feature of CAFE is the multiparty security. No mutual trust between parties of conflicting interest is assumed.

CAFE is an open secure system. It supports multiple issuers of electronic value and multiple currencies,

including currency exchange during a payment. It provides the customer with a history log of their payments. The system uses public key signature and encryption and allows for offline purchase transactions. The basic purchase transaction mode is anonymous and untraceable for the customer and performed offline; there is no need to connect to a third party online. Withdrawals and deposits are identified, traceable, and online. If payments exceeding a certain level must be confirmed, then some online interaction becomes necessary.

CAFE provides recovery of lost, stolen, and damaged cards. Although prepaid, it is loss-tolerant and allows customers to recover their money if they lose their cards, because an encrypted version of all tokens issued to the customer is held in a safe place. The customer must surrender his or her anonymity and untraceability, then the issued token backup can be decrypted and matched against the redeemed token database. To provide some loss tolerance for stolen cards, the customer must authenticate himself or herself via a pass phrase (PIN) prior to a purchase.

The device receives coins by withdrawing them from the issuer account via an ATM using the blind signature method known from ECash. CAFE is prepaid, and the tokens on the device do not exist as currency anywhere else. When the customer spends money, the device transmits one or more tokens to the merchant and marks on the device them as spent. Transmissions are performed contact-less via infrared channels. The merchant then owns the value of those tokens, which need to be deposited with an acquirer and accepted by the issuer for that value to be realized for the merchant. Thus, the primary flow of value in CAFE is that of withdraw, pay, and deposit—that is, the payment model is the typical direct cash-like approach.

The basic hardware device is a pocket calculator-like electronic wallet, to be used for customer payments, to access information services, and for identification. It aims to be nonproprietary. The electronic wallets and smart cards—that is, the hardware—should become standardized and be available in shops just like other electronic consumer goods. The wallet contains a so-called guardian, a smart card with a dedicated cryptographic processor. The wallet protects the interests of the customer, the guardian protects the interests of the money issuer, and both are holding part of each token withdrawn. No transactions are possible without the cooperation of the guardian; the guardian maintains a record of all the tokens spent to avoid double spending. The guardian chip authorizes each payment by signing it. CAFE tokens do not remain in circulation like real cash tokens do. Re-spendability is broken explicitly—the wallet signs to whom it pays a token, so only that payee can deposit the token.

As a fallback, when the guardian is compromised CAFE uses so-called offline digital coins that provide a once-concealed, twice-revealed feature. The money is encrypted, and the identity of the customer signed by that customer is encoded into the token number. This is done in a way that the identity of the customer can be recovered only if the customer double spends. This feature works as follows: When the customer uses a token in payment, it is challenged by the merchant to reveal a

²DigiCash is the company that pioneered electronic cash systems. It was founded by David Chaum, who is widely credited with being the first to propose an anonymous electronic cash system. Interested readers are directed to articles by Chaum (1982) and Chaum, Fiat, and Naor (1988).

certain part of the encoded customer identity. One part on its own does not reveal anything useful. If, however, the customer tries to re-spend the same token, another part of the customer identity is revealed to the merchant; now, with a high probability, the identity of the customer can be traced. In order to do this, the issuer must hold a database of all reimbursed tokens that it already needs for the fault-tolerance feature.

As a fixed-denomination token system that distinguishes between customers and merchants, CAFE needs to address the problem of making change. It allows the construction of coins that can be split into smaller coins if need be and of coins that—being more expensive than their denomination—may be spent more than once. These measurements reduce the unlinkability of the payments but not their integrity. For repeated very small payments to the same merchant, so-called phone ticks, CAFE provides a special way of surrendering a token in installments.

In CAFE, transactions appear atomic to the user but not to the merchant. The tokens a merchant accepts in payment must be deposited with an acquirer and accepted by the issuer before their monetary value can be realized by the merchant. The value leaves the customer, but does not immediately arrive at the merchant.

Micropayment Systems

MilliCent

MilliCent (Manasse 1997) is the most widely known micropayment scheme. MilliCent is a proprietary voucher-based digital micro commerce system from the erstwhile Digital Equipment Corporation (acquired by Compaq and now part of HP Invent). It aims at the micropayment segment of electronic commerce and supports transactions with values of fractions of a cent. MilliCent considers that coins are treated differently than paper money, in the same manner that small-denomination notes are treated differently than high-denomination notes. Because MilliCent represents very small coins, it uses lightweight security measures. A public trial of the MilliCent system involving toy money started in December 1997.

The system uses merchant-specific vouchers, the so-called scrip, which is a form of token that is valid only with a particular merchant for a limited period. Brokers act as intermediaries between merchants and customers. The fact that any type of scrip is valid only at a particular merchant means that the merchant does not need to connect to a central issuer to validate the token. This reduces network traffic and the validation cost. To avoid customers having to maintain separate accounts with the individual merchants for mostly short-term relationships, brokers act as intermediaries. The long-term relationships are between brokers and customers, and brokers and merchants. Consumers register with one broker and buy broker scrips in bulk—generic scrip. Brokers receive payment from consumers in a variety of ways, but the most common way the consumers pay is with a credit card. When a consumer locates a product on a merchant's Web site that he or she would like to purchase, the consumer converts the broker scrip into vendor-specific scrip. Vendor-specific scrip is scrip that a particular merchant will accept.

The consumer's new scrip is stored in an electronic wallet on the consumer's computer. Paying for an item involves simply transferring a merchant's scrip, which is in a consumer's wallet, to the merchant in exchange for a purchased item. Merchants can then send a broker their own scrip and obtain a check. The basic sequence of interactions is as follows:

1. The customer obtains a quantity of broker scrip at the outset.
2. The customer requests some specific vendor scrip, which they will pay for later with the broker scrip.
3. The broker obtains the required vendor scrip from the vendor.
4. The broker sells the vendor scrip to the customer.
5. The customer buys the service with the vendor scrip.
6. The vendor gives change in vendor scrip.

Steps 1 to 4 are not required for every transaction; the customer can buy sufficient scrip from the broker for a period. Likewise, the broker can store enough vendor scrip to serve many customer requests or it can have a license from the vendor to create that vendor scrip directly. Although at first glance a lot of message passing seems to be required, there is no bottleneck like one single currency issuer to be contacted during each transaction, especially once steps 1 to 4 are completed. Experiments at Digital indicate that MilliCent is efficient enough for transactions as low as one-tenth of a cent. A broker is required in the protocol for two reasons. First, the system of very small payments works because transactions can be aggregated so they are significant. That is, when a consumer buys a few dollars worth of scrip, there is little profit in the deal. However, when several consumers purchase scrip, the aggregate amount—even discounted so that the broker can make money—does make economic sense. The second reason for a broker is that it makes the entire system easier to use. A consumer has to deal with only one broker to satisfy his or her scrip needs for many merchants. The broker buys the scrip in bulk and does all the hard work of organizing the retail selling to customers.

A significant feature of the MilliCent protocol is the trade-offs attempted at different points in the design. For example, MilliCent offers three protocol versions—"private and secure," "secure without encryption," and "scrip in the clear." The least secure is "scrip in the clear." Here, the scrip is transferred between customer and vendor without any encryption or protection; thus, the protocol is the most efficient and cheapest to implement. However, this allows any observer to change the scrip or replay it and spend it itself. Thus, the customer can potentially suffer a financial loss. Although amounts stolen this way will be quite small, it can be rather annoying to the customer to find their small change to be invalid. The next level of security is provided by "secure without encryption." Here, personal information about the customer that is carried by a field in the scrip is available to the player involved in the scrip system; however, the scrip itself is protected from replays that allow an observer to spend the scrip itself. The most secure is the "private and secure" version of the protocol.

However, it too uses lightweight encryption technology, which is probably not too difficult to break. The philosophy is that the cost of breaking the protocol should be greater than the value of the scrip itself. Scrips can be minted at very low value. Thus, loss of scrip due to confidentiality or integrity breaches does not cause significant financial loss to the end user.

Stored-Value Card Systems

MONDEX

The most well known example of an electronic purse or stored-value card system is the MONDEX smart card—a service of MasterCard International (2004). It was introduced in the early 1990s; it is the largest pilot program of an electronic purse product to date. The MONDEX smart card contains a microcomputer chip. The card can accept electronic cash directly from a user's bank account. Cardholders can spend their electronic cash with any merchant who has a MONDEX card reader. Two cardholders can even transfer cash between their cards over a telephone line. A single card works in both the online world of the Internet and the offline world of ordinary merchant stores while simultaneously being impervious to the theft threats of credit cards. Another advantage of MONDEX is that the cardholder always has the correct change for vending machines of various types. MONDEX electronic cash supports micropayments as small as 3 cents. MONDEX has lower per-transaction costs than credit or debit cards, since value transfers take place locally, just as for cash. Thus, it is a good choice for minipayments and micropayments. Finally, MONDEX has the ability to provide user anonymity. This is because, just like cash systems, MONDEX does not maintain any audit record. MONDEX has some disadvantages, too. The card carries real cash in electronic form, and the risk of theft of the card may deter users from loading it with a significant amount of money. Moreover, MONDEX cannot compare with credit cards in the area of deferred payment. One can defer paying his or her charge or credit card bill for almost a month without incurring any interest. MONDEX cards dispense their cash immediately. Last but not least, a MONDEX card requires special equipment; merchants who accept it must have a specific card reader at their checkout counter. A MONDEX card must also be in physical contact with a special card reading and writing device during a merchant or recharge transaction. Internet users can transfer cash over the Internet using MONDEX, but they must attach a MONDEX reader with their PC in order to use the card. These requirements have proven to be barriers to the widespread use and success of MONDEX.

A MONDEX transaction consists of several steps. These steps ensure that the transferred cash reaches the correct destination in a safe and secure manner. Following are the steps to transfer electronic cash from the buyer to the seller.

1. The card user inserts the MONDEX card into a reader. The merchant and the card user are both validated to ensure that both the user and the merchant are still authorized to make transactions.
2. The merchant's terminal requests payment while simultaneously transmitting the merchant's digital signature.
3. The customer's card checks the merchant's digital signature. If the signature is valid, then the transaction amount is deducted from the cardholder's card.
4. The merchant's terminal checks the customer's just-sent customer digital signature for authenticity. If the cardholder's signature is validated, the merchant's terminal acknowledges the cardholder's signature by again sending back to the cardholder's card the merchant's signature.
5. Once the electronic cash is deducted from the cardholder's card, the same amount is credited to the merchant's electronic cash account. Serializing the debit and credit events before completing a transaction eliminates the creation or loss of cash if the system malfunctions in the middle of the process.

Currently, only a few cities in the United States accept MONDEX. Worldwide, MONDEX is available in several countries on the North and South American continents, Europe, Africa, the Middle East, Asia, Australia, and New Zealand. As a whole, stored-value cards are not yet very popular in the United States, where people still prefer credit cards rather than smart cards.

Electronic Check Systems

ECheck

The most well known among the electronic check systems is eCheck (Financial Services Technology Consortium 2002). It combines "the security, speed and processing efficiencies of all-electronic transactions with the familiar and well-developed legal infrastructures and business processes associated with paper checks" (www.echeck.org). An eCheck is the electronic version of a standard paper check. It contains the same information as paper checks contain. It is based on the financial services markup language (FSML). It provides strong authentication, strong encryption, and duplicate detection features. It can be used with existing checking accounts, has unlimited but controlled information-carrying capability, and has some enhanced capabilities, such as effective dating, that are not provided in traditional checks. In addition, eCheck is often considered more secure than traditional paper checks. In eCheck, each electronic checkbook is assigned a unique eCheck account number that only the bank can map into the actual underlying account number. This account number is part of the distinguished name in the bank-issued account certificate, so it cannot be modified but is easily verified by anyone who receives an eCheck. Thus, compromise of an eCheck does not lead to possible compromise of the underlying account. Revoking an eCheck account number has no impact on the underlying account.

ECheck is the first and only electronic payment mechanism chosen by the U.S. Treasury to make high-value payments over the Internet. It is currently under enhancement in Singapore and is being considered for many online systems.

Mobile Payment Systems

FeliCa Card

The FeliCa card is a contact-less smart card developed by SONY Corporation to be used as an electronic purse. It operates in the 13.56-MHz frequency range and has an operation range of a few centimeters. It uses the ISO 7810 form for credit cards. The FeliCa card was first used in the Hong Kong Octopus card system for public transportation. Later it was used in many other systems, including EZ-link in Singapore, most mass-transit system in Japan, and the New Delhi Metro in India. Mobile FeliCa is a modification of FeliCa for use in mobile phones. Mobile FeliCa-equipped mobile phones can potentially be used as prepaid electronic cash, tickets, membership cards for clubs, and credit and debit cards. Pilot projects are currently under way in Japan. However, the proprietary technology is hindering widespread adoption.

ExxonMobil Speedpass

ExxonMobil was one of the first to introduce a contact-less electronic payment system to help consumers make retail purchase. Called Speedpass, it uses a proprietary radio-frequency communication technology and is a proximity card. A customer opens a Speedpass account that is linked to the customer's credit or check card. The radio-frequency payment device comes as a key fob, a watch, or a transponder affixed to the customer's vehicle's rear window. The payment terminal is integrated into the gas pump. At the beginning of a transaction, the payment terminal authenticates the Speedpass device and authorizes a charge. The charge gets reflected directly into the user's credit/check card account. Although initially intended for purchases made at a pump, Speedpass is increasingly being accepted at convenience stores for retail purchase.

CONCLUSION AND FURTHER READING

In this chapter, we presented an overview of electronic payment systems. One of our objectives was to identify the technical challenges, mostly security-related, that hinder the widespread deployment of such systems. We also surveyed some of the more well known instances of electronic payment systems. Our survey is by no means complete. Many new systems are proposed on a regular basis. The majority of them do not survive market forces. Those that do frequently are acquired by the bigger players, and their initial business focus gets lost.

A good source of information for electronic payment systems is Dr. Phillip M. Hallam-Baker's Web page on *Electronic Payment Schemes* (Hallam-Baker 2004) on the W3 Consortium. This page categorizes electronic payment schemes along two dimensions—the level of abstraction for the payment scheme (namely, *policy*, the semantics of the payment scheme; *data flow*, the requirements for storage of data and communication between parties; and *mechanism*, the security methods used), and the payment model for the protocol (namely, cash, check, or card). The Web page contains a comprehensive list of Internet payment schemes and protocols. The author makes an

earnest effort to keep the list as up-to-date as possible; however, this may not always be possible. The CAFE project of the European Community's ESPRIT program (1995) and the SEMPER project of the European Commission's ACTS Program (2000) are two important European projects that provide valuable information on electronic payment systems. The list maintained by the SIRENE (2004) group is also a valuable resource for electronic payment systems. Leo Van Hove's (2004) database on E-purse provides a collection of links and references on electronic purses (and related issues). The E-money mini FAQ page (Miller 2004) written by Jim Miller and maintained by Roy Davies, provides answers to some frequently asked questions about electronic money and digital cash. Roy Davies also maintains a comprehensive information resource for electronic money and digital cash (Davies 2004). The Financial Services Technology Consortium (FSTC) has several projects (both past and present) aimed at developing technologies that facilitate electronic payment systems. Information about these projects can be found from the FSTC Projects Web page at www.fstc.org/projects. For a comprehensive (although somewhat dated) overview of contact-less payment systems, readers are directed to the Smart Card Alliance (www.smartcardalliance.org) report PT-03002, dated March 2003, "Contactless Payment and the Retail Point of Sale: Applications, Technologies and Transaction Models." Finally, some useful reference books for electronic commerce and electronic payment systems, are the books by Bidgoli (2002), Schneider (2006), Turban et al. (2005), and van Slyke and Belanger (2002).

GLOSSARY

Acquirer: The entity or entities that hold(s) deposit accounts for card acceptors (merchants) and to which the card acceptor transmits the data relating to the transaction; the acquirer is responsible for the collection of transaction information and settlement with acceptors.

Audit Trail: A sequential record of events that have occurred in a system.

Automated Clearinghouse: An electronic rendezvous for financial institutions where payment orders are exchanged among the financial institutions primarily via magnetic media or communications network. Commonly known as ACH.

Automated Teller Machine: An electromechanical device that permits authorized users to use machine-readable plastic cards to withdraw cash from their accounts at a particular financial institution and/or access other services, such as account balance enquiries, transfer funds between accounts, or deposit money into accounts.

Batch Processing: The transmission or processing of a group of payment orders as a set at discrete intervals of time.

Card: A general term used to describe several types of payment systems, including ATM card or cash card, check guarantee card, chip card (or smart card), credit card, charge card, debit card, delayed debit card, prepaid card, retailer card, and stored-value card.

Cash Card: Card for use only in ATMs or cash dispensers.

Certificate: A document (physical or electronic) that evidences the undertakings of an issuer.

Charge Card: Card issued by nonbanks indicating that the holder has been granted a line of credit. It enables the holder to make purchases but does not offer extended credit, the full amount of the debt incurred having to be settled at the end of a specified period. Typically issued by the travel and entertainment industry to their customers.

Check: A written order from one party (the drawer) to another (the drawee, normally a bank) requiring the drawee to pay a specified sum on demand to the drawer or a third party of the drawer's choosing. Checks may be used for settling debts and withdrawing money from banks.

Check Card: A card issued as part of a check guarantee system.

Check Guarantee System: A system to guarantee checks, typically up to a specified amount by the issuer of the guarantee card.

Chip Card: See *Smart Card*.

Clearing/Clearance: The process of transmitting, reconciling, and, in some cases, confirming payment orders or security transfer instructions prior to settlement.

Credit Card: A card indicating that the holder has been granted a line of credit. It enables the holder to make purchases and/or withdraw cash up to a prearranged ceiling; the credit granted can be settled in full by the end of a specified period or can be settled in part, with the balance taken as extended credit.

Credit-Card Company: A company that owns the trademark of a particular credit card, and may also provide a number of marketing, processing, or other services to its members using the card services.

Debit Card: A card that enables the holder to have his/her purchases directly charged to funds available in his/her account at a deposit-taking financial institution.

Delayed Debit Card: A card issued by banks indicating that the holder may charge his/her account up to an authorized limit. It enables the holder to make purchases but does not offer extended credit; the full amount of the debt incurred needs to be settled at the end of the specified period.

Electronic Fund Transfer System: A formal arrangement based on private contract or statute law with multiple membership, common rules, and standardized arrangements, for the electronic transmission and settlement of monetary obligations.

Electronic Payment System: An electronic system consisting of a set of instruments, banking procedures, and typically interbank fund transfer systems that ensure the circulation of money.

Electronic Purse: A reloadable multipurpose prepaid card that may be used for small retail or other payments instead of coins.

Electronic Wallet: A computer device used in some electronic payment systems to store information that is needed to undertake a financial transaction.

Magnetic Ink Character Recognition: A technique using machine-readable characters imprinted on a

document using an ink with magnetic properties by which information on the document is interpreted by machines for electronic processing. Also known as MICR.

Micropayment: A method of payment for very small sums of money where the cost of making the payment using traditional means—like check, credit or debit cards, etc.—far exceeds the value conveyed in the payment. Typically, the amount transacted is on the order of several cents to at most a few dollars (<10) only.

Payment: The process of the payer's transfer of a monetary claim on a party acceptable to the payee.

PIN: A numeric code that a cardholder may need to quote for verification of identity. It is often seen as the equivalent of a signature.

Prepaid Card: A card on which value is stored and for which the holder has paid the issuer in advance. Also known as stored-value card.

Provider: The operator who establishes the hardware and software conditions for the conduct of transactions with electronic money without necessarily being the issuer of the electronic money units.

Scrip: A form of micropayment token (voucher) that is valid only with a particular merchant for a limited period.

Settlement: The act of discharging obligations with respect to fund transfers between two or more parties.

Smart Card: A card with a built-in microprocessor and memory that is capable of performing calculations and storing information.

SSL: Secure sockets layer. A cryptographic protocol used for exchanging information between a client and a server over the Internet in a secure and authenticated manner.

A SOCIAL HISTORY OF INTERNET RELAY CHAT

From the earliest days of Internet-based communication, Unix systems have included a variant of the *talk* program. This program simply divides two users' computer terminals in half. Each user types in one half of the screen, and the other user immediately sees these keystrokes. Over time, the *talk* program evolved into *ytalk*, which allowed more than two users to communicate at one time. In 1988, Jarkko Oikarinen (n.d.) built on this idea to create Internet relay chat (IRC). Although Oikarinen points out that earlier chat programs existed, this is largely recognized as the beginning of Internet chat. Chat has evolved in a number of ways since the creation of IRC (e.g., Churchill et al. 2000; Farnham et al. 2000; Erickson et al. 2002; Smith, Cadiz, and Burkhalter 2002), the fundamental features have not changed.

In text-based chat programs like IRC, a number of users can connect into the same virtual space and communicate with one another in near real time using text. Unlike *talk* and *ytalk*, IRC sends completed messages over the network, rather than individual keystrokes. In other words, most chat programs allow interlocutors to compose comments in private, which are not revealed to others until the user presses the *Enter* key. As we will describe in more detail later, this design feature has significant implications for the psychology of interaction in IRC. In the conversation window, new comments are typically placed on the bottom of the screen when they arrive, causing older messages to scroll off of the top of the screen.

Created in 1988, IRC's popularity grew enormously during the early 1990s. IRC gained notoriety as a strategic global communication system in 1991, when real-time messages were received from IRC users inside Kuwait during the Iraqi occupation. In 1993, IRC enabled computer users in Moscow to communicate with outsiders during the uprising against President Yeltsin. Following the terrorist attacks in New York and Washington in September 2001, IRC networks became extremely active, initially to support communication with survivors and rescue workers, and later to allow users from around the globe to vent their feelings, rally support for victims, and

engage in political and ideological debate. When other communication systems failed or became congested during these international crises, computer users with access to the Internet used IRC for up-to-the-minute interaction with external parties. In recent years, however, easy-to-use Web-based chat systems and instant messaging have largely contributed to a significant decline in IRC's popularity. Unfortunately, because of the distributed nature of IRC networks, few concrete statistics exist about its popularity and use.

TECHNICAL DETAILS

Servers, Networks, and Channels

IRC is built on a fairly standard client/server framework. The IRC server is the central point of communication through which all messages pass en route to individual client computers. In the simplest IRC network structure, each user's computer runs a client program to connect to a common server. The server runs an application called an IRC daemon (IRCD), which allows connections from individual users and relays messages from one client to another by passing them through the server. Some IRC chat systems consist of a simple network in which a single server manages connections and communications among all its clients. However, most IRC servers are connected to other IRC servers, thus opening the IRC system to potential communication among all users with connections to all the servers on the network.

The details of the communication protocol were originally laid out in RFC 1459 in 1993. Seven years later, this protocol was updated to RFC 2810, RFC 2811, RFC 2812, and RFC 2813, reflecting the growing use of file sharing and other enhancements. Although IRC technically refers to any system built using this communication protocol, most people use the term to refer to a handful of large networks of servers, such as EFnet or IRCnet. Originally, there was only one IRC network, consisting of a few servers, but as IRC grew in popularity and complexity, it splintered into multiple networks. Today there are hundreds of IRC networks that are constantly evolving through expansion and redefinition. They range in size from very small, family-oriented chat networks, to such

Table 1: Some of the Largest IRC Networks

	Number of Servers	Help Site and Server List
Efnet	40	www.efnet.org
IRCnet	>120	www.ircnet.com
DALnet	30	www.dal.net
Undernet	40	www.undernet.org
GalaxyNet	30	www.galaxynet.org
WebNet	15	www.webchat.org
NewNet	15	www.newnet.net
ChatNet	15	www.chatnet.com

global networks as EFnet or the expansive IRCnet, which links well over 100 servers and supports thousands of chat groups, or *channels* (see Table 1).

To engage in IRC, users select an IRC network and connect to one of the available servers, using a nickname (e.g., *SuperTig*) rather than their real name. Unlike many modern communication systems, however, users do not have to register their nickname. Instead, they can choose any nickname they want as long as no one else on the network is already using that nickname. Until 1994, there was a system called NickServ, however, that allowed users to register nicknames, but it worked a little differently than might be expected. If a nickname was registered, any user could still log onto an IRC network with that nickname. If the registered owner of that nickname happened to log

onto that same network, however, he or she could reclaim this nickname and force the other user to change his or her nickname to something else. There is no evidence that NickServ will resume.

Upon logging onto an IRC network, users typically receive the MOTD (message of the day) containing some basic information from the server's database about the channel's current activity (topic, nicknames of current users, etc.). Using the `/list` command, users can consult a list of public chat rooms, known as channels, currently available on that server, which can they can join using the command `/join #channelname`. The channels listed as `#channelname` are global and can be accessed through any server on the network; channels listed as `&channelname` are available through that server alone. Some channels are designated "secret" and are not open to others. Channels exist only when they are used. In other words, users can create new channels simply by attempting to join one that does not exist. Similarly, channels disappear when the last user leaves. Having joined a channel, the new user is then ready to communicate with others by sending a message that will appear more or less synchronously on the screens of all channel participants (see Figure 1). The command `/leave` or `/part` will terminate the connection to the channel, and the command `/quit` will terminate the connection to the network.

In reality, connecting to an IRC server is not always simple, especially for newcomers. Connection may be prevented if the user enters an incorrect server name, chooses an unacceptable nickname, or has been *K-lined* (specifically banned from the server for some reason). Users who connect to the Internet through large, popular ISPs (Internet service providers) may find some channels closed to them, based on the stereotype that

**Figure 1:** Screenshot of online interaction using mIRC

such subscribers are probably newbies and therefore unwelcome on certain channels.

IRC networks are not immune to problems of congestion or breakdown. As with all other packet-switching Internet communication systems, users sometimes experience delays in the transmission of electronic messages. This delay (known to IRC users as “lag”) is irritating to all Internet users, but it is especially problematic in synchronous communication systems characterized by real-time interaction. A 10-second lag can dramatically change the timing and effectiveness of some types of online interaction, as threads of conversation become entangled and users appear to be “talking over” one another. The jumble of multiple conversations is a common characteristic of interaction on public IRC channels (Herring 1999, Interactional coherence in CMC), and lag serves to exacerbate the problem. Increased lag may be caused by heavy traffic on the Internet or IRC network, a malfunctioning server, flooding, or a denial of service attack (see below). Lag is sometimes related to a netsplit, which occurs when one or more IRC servers lose their connection to the network. Netsplits fracture the network and effectively create separate network fragments that may or may not continue to operate separately. Netsplits often result in a buildup of packets queued for delivery to servers that are no longer available. After a netsplit, servers sometimes reconnect to the network and are able to update the server with activity that occurred during the netsplit. Sometimes a netsplit results when an IRC operator revises the network's connection to other servers in order to achieve a more efficient or more desirable network configuration.

Although IRC communication was intended to flow through servers, a new form of communication, known as direct client connection (DCC), emerged in the late 1990s. Two clients who are connected to the same IRC network can initiate a direct connection between each other. IP (Internet protocol) addresses are typically used to establish the DCC connection, and messages or shared files pass directly from one client to the other without being relayed by the IRC server. Many of the more experienced users prefer to use DCC for their one-on-one interactions and file transfers, because DCC frequently results in faster message exchange, a higher degree of privacy, and avoidance of network problems such as lags and netsplits.

IRC Client Software

In order to engage in online communication using IRC, users need access to the Internet through an ISP or direct network connection. They must also install a communications software program called an IRC client. The client software serves as the interface between the individual computer (the client) and the IRC server (serving the needs of multiple clients). The IRC client processes the commands that are typed or clicked by the user and then uses network protocols, such as TCP/IP (transfer control protocol/Internet protocol) to transmit them to the server.

IRC supports communication across different operating platforms, enabling the flow of messages between PC and Macintosh computers, as well as UNIX-based computing systems. IRC clients for these and other operating

systems are readily available, and free downloads or demonstration copies can be found on most of the major FTP (file transfer protocol) sites on the Internet. Some IRC clients are available as shareware, meaning that after a free trial period, if users wish to continue using it, they are asked to purchase the software or pay a modest registration fee. Generally, the cost of IRC client software is quite reasonable.

Text-Based IRC Clients

Early IRC users were almost exclusively UNIX-based, and the majority of today's IRC servers are UNIX servers. Individual computer users who use a terminal-emulation program to establish a dial-in connection to an organization for Internet access effectively turn their computer into a terminal making use of a shell account on the UNIX system. The most common IRC client for UNIX and related systems (such as shell accounts and Linux) is IRCII. This full-featured, text-based client was the first widely used IRC client and still serves as a reference standard for essential commands and functions. More advanced users sometimes use IRCII's scripting language to create scripts that streamline complex processes, generate customized output, or perform certain functions automatically when prescribed conditions occur.

Graphical Interface IRC Clients

The majority of online communicators connect to the Internet through Windows-based PCs or Macintosh computers. IRC clients have been developed for both platforms, offering the point-and-click ease-of-use characteristic of graphical user interfaces (GUIs). The major GUI clients receive ongoing attention from their developers, and excellent support is available for learners. The client of choice for many PC users using Windows operating systems is mIRC, a powerful, intuitive, and reliable application. Because PC users outnumber those on UNIX and Macintosh platforms, mIRC is probably the most widely used IRC client on the Internet today. Easy-to-use menus and buttons, customizable functions, and extensive user support contribute to the popularity of mIRC (see Figure 1). The most widely used IRC client for Macintosh computers is Ircl. A stable, full-featured IRC client, Ircl provides buttons, menus, and icons to facilitate common IRC functions. Ircl users may also use AppleScript to modify the client to their custom specifications. Good user support and innovative features place IRC interactions within easy reach even for beginning Ircl users.

IRCops, Chanops, and Users

The IRC system hierarchy of networks, servers, channels, and clients is reflected in an administrative hierarchy of people who oversee each level of the system. End users who direct their IRC client to connect to a network should be aware of the scope of authority and control exerted by IRC operators and channel operators. Newbies sometimes embarrass themselves and irritate others by inappropriately posing questions or filing complaints with the person they perceive to be in charge of a channel or server.

IRCops

IRC operators generally oversee the operation of an IRC server, maintain routing functions in relation to other servers on the network, modify server settings, and monitor general activity on the server. Sometimes the original server administrator fulfills the role of IRCop, and sometimes the administrator selects one or more experienced and qualified users to serve as IRCop. Servers typically have more than one operator, in order to ensure constant observation of activity on the server. In the event of a server failure or network fault, IRCops work to restore network connections. They also enforce the policies and procedures of the server they oversee. If a user violates policy or misbehaves in some way, the IRCop usually issues a warning. Users who are reprimanded by an IRCop are sometimes unaware of the power the operator has to control activity on the server. For example, an IRCop can issue a */kill* command that effectively bans the offending user from further access to the server and, in some cases, the entire network. Determining the identity of a server's IRCops is not always easy. When they are listed in the MOTD (message of the day) or active user lists, their "user mask" (nickname plus host name) is usually marked with an asterisk (**Stinkbug!skb220@rhl.net*). The command */stats o* may be used to identify active operators, and some IRC clients support the command */who -oper*. Many IRC users never have direct communication with an IRC operator unless their activity on the server violates accepted practice and attracts the operator's attention. IRC operators do not exert control over channel activities; they leave those functions to the channel operators.

Chanops

Each IRC channel (chat group) is initiated or overseen by a channel operator, or chanop. Channel operators exert management and control over the channel's topic, mode, and settings, and they regulate how many users and, specifically, which users are allowed to interact on the channel. If users misbehave, become obnoxious, or simply irritate the channel operator, most chanops do not hesitate to ban them from the channel. Any IRC user who creates a new channel with the */join #channelname* command automatically becomes the operator for that channel. Because of this, it is not uncommon for chanops to misbehave as well (Herring 1999, The rhetorical dynamics of gender harassment on-line). Chanop status is valid only for the duration of the current IRC session, and when chanops leave the channel, they ordinarily lose their operator status. However, if operators are registered as super-ops with an IRC channel service, they can effectively maintain control over a channel even during their absence. Many IRC channels have several operators active at any given time, but occasionally a channel may function with no operator. Channel operators are usually identified with an @ sign before their nickname (*@Super-Tig*). Most IRC clients support the command */who -chops* as a means of identifying channel operators.

Chanops can remove users from a channel and ban them from future access. On password-protected channels, they can invite users to join and can issue them the key to enter. On moderated channels, chanops can

give selected users a voice that allows them to post messages to the channel while other users can only receive messages. Channel operators can grant chanop status to other users, and they can remove chanop status from other operators. When a new channel is created, some basic channel modes and settings should immediately be set to establish guidelines for the activity allowed by users and operators on the channel.

Common User Commands

Table 2 contains a sampling of user commands commonly used across different IRC clients and servers. Users of text-based clients enter these commands manually, whereas users of GUI clients usually click on icons or dropdown menus to engage the function, and the client automatically generates the command. Some commands contain specific parameters or are qualified by "flags" that set the limits of the command output. Table 3 contains the most common commands used by channel operators.

IRC AND CONVERSATIONAL DYNAMICS

As with all online communication systems, IRC is more than a network of computers relaying electronic files among themselves. Fundamentally, IRC systems are composed of humans who use the computer network to exchange information or conversation with others. As a somewhat specialized online community, IRC has drawn those who are more technically proficient, whose computer skills enable them to easily perform tasks such as downloading and installing software from an FTP site; learning intuitively the features and functions of new software applications; using line commands, scripting, or hand coding to accomplish tasks; adapting to the specific styles and conventions of online communication forums; and maintaining sufficient safeguards to protect their personal privacy and system security.

Many individuals "meet" regularly on IRC channels, where, in much the same way as with instant messaging and Web chat, they develop close relationships and a true sense of community. On some channels, the basis for commonality is the agreed-upon topic (such as advanced applications of certain software), and participants willingly share techniques and resources in mutual support of one another. Other channels are predominantly social in nature, marked by spontaneous casual conversation. In both types of IRC communities, casual online acquaintances are the norm, but significant one-on-one relationships sometimes develop. There are reports of IRC users who decided to move their relationships offline and meet face to face, and some have become business partners or marriage partners (e.g., Hoff and Hoff 1999). Of course, the majority of IRC relationships are restricted to the online context, but they constitute legitimate relationships that fill meaningful social roles for many users. Friends made on IRC are not only "virtual" friends but also "real" friends.

Although there are some resemblances to other communication media, text-based chat technologies represent a new form of interaction.

Table 2: Basic User Commands

<i>/join #channelName</i>	Joins the user to a global channel on the network, unless the user is banned or the channel is restricted (invite-only, secret, etc.).
<i>/join channel1, #channel2</i>	Allows the user to simultaneously participate in both of the channels listed.
<i>/mode MyNickname +i</i>	Sets the mode of the user “MyNickname” to invisible, enhancing privacy and security.
<i>/list</i>	Produces a list of channels on the server; often used with various flags and parameters.
<i>/set hold_mode on</i>	Prevents a long list from scrolling beyond the monitor’s limits.
<i>/names</i>	Shows a list of nicknames of users currently on the network (potentially a huge listing, so always use parameters).
<i>/names #channelName</i>	Shows a list of nicknames of users currently on the channel (also very large on some channels, so use parameters).
<i>/who #channelName</i>	Lists nicknames, usermasks, and other information about current users on a channel.
<i>/whois NewName</i>	Produces basic information from the server’s database about the user “NewName.”
<i>/msg NewName</i>	Sends a private message to the user NewName; messages to all users are entered without the <i>/msg</i> command.
<i>/dcc chat NewName</i>	Requests direct client connection with the user “NewName”; if NewName accepts, a direct private chat will bypass the IRC server (may be more private, have less lag).
<i>/nick othername</i>	Changes a user’s nickname to the one specified.
<i>/ignore badguy</i>	Blocks or ignores messages from user called “badguy.”
<i>/part or /leave</i>	Signs a user off of a channel; may be followed by a parting comment.
<i>/quit</i>	Terminates connection to the network; may include a brief comment.

Table 3: Basic Channel Operator Commands

<i>/join #NewChannel</i>	Creates a new channel with the specified name.
<i>/mode #NewChannel +o l m v t</i>	Sets the channel modes to Operator (chanop status can be assigned or removed), Limit (limits the number of users allowed at one time), Moderated (all users receive, but only some can post messages), Voice (grants selected users the ability to post messages), and Topic (set by operators only); several other modes are available.
<i>/mode #NewChannel</i>	Reveals all the current mode settings for the channel.
<i>/mode #NewChannel +o mybuddy</i>	Gives the user “mybuddy” operator status.
<i>/mode #NewChannel -o mybuddy</i>	Removes chanop status from the user “mybuddy.”
<i>/mode #NewChannel +l 20</i>	Limits the number of users on NewChannel to 20.
<i>/mode #NewChannel -l</i>	Removes the limit on number of users.
<i>/mode #NewChannel +v angelbaby</i>	Allows the user “angelbaby” to post messages to NewChannel.
<i>/topic #NewChannel IRC clients</i>	Changes channel topic to “IRC clients.”
<i>/kick #NewChannel satanson</i>	Kicks the user “satanson” off the channel.
<i>/invite mybuddy #NewChannel</i>	Invites the user “mybuddy” to join NewChannel.

Linguistic Features of Chat Conversations

Because chat messages are composed before being displayed, the usual turn-taking mechanisms that provide for an orderly conversation (Grice 1975) break down. Chat messages appear in the temporal order in which the chat server receives them; several conversational turns may occur between a comment and its response. Because there are no mechanisms for the orderly exchange of the conversational floor—a linguistic term describing the social conventions that control who is expected to speak (or not) at any given point in time—threads of discussion tend to interleave in chat environments (Werry 1996). Although this has led many to speculate about the difficulties that can arise from these new threading structures (e.g., Farnham et al. 2000; Smith et al. 2002), reports of smaller group (i.e., less than about 15 people) discussions rarely identify this as a problem (e.g., McDaniel, Olson, and Magee 1996). Herring (1999, Interactional coherence in CMC), having analyzed this lack of interactional coherence related to threading structures, suggests that the popularity of chat in spite of this limitation may have to do with the new types of linguistic play enabled, such as the ability to participate in multiple “conversations” at once.

The linguistic structure of chat interaction tends to look somewhat like that of face-to-face interaction (Condon and Cech 1996), with some notable exceptions. Because the usual nonverbal behaviors are absent in the online context, a greater responsibility is placed on verbal messages for feedback, affect, and nuances of meaning. Typically, IRC users attempt to replace nonverbal messages through various means (Werry 1996), such as using acronyms like IMHO (“in my humble opinion”) and LOL (“laughing out loud”), or by inserting affect cues <grin>, demonstrative punctuation (no!!!!!!!!!!), or emoticons such as the smiley face :-) and its many variant forms. These abbreviations also serve as important linguistic markers to identify membership in a social in-group (Wenger 1998; Cherny 1999; Sassenberg 2002). Because of the reduced efficiency involved in typing, chat conversations typically omit unnecessary linguistic information, such as some grammatical structures and elaborations/repeats of ideas (Condon and Cech 1996).

Behavioral Features of Chat Conversations

Communication researchers study the social, relational, and communicative dynamics of online communication forums such as IRC. Overall, these studies indicate that computer-mediated communication (CMC) systems do support the development of meaningful relationships, effective decision-making groups, and a legitimate sense of community (Finholt, Sproull, and Kiesler 1990; Reid 1991; Walther 1996, 1997; Wood and Smith 2001). Nevertheless, research has also identified some important differences between face-to-face and online communication. For example, in face-to-face interactions, people normally communicate interpersonal liking through nonverbal cues such as eye contact, smiles, proximity, touch, open body positioning, and vocal expressiveness (Richmond and McCroskey 1999), but these are all re-created in new ways online (Walther 1996). The absence of nonverbal

communication cues led some early researchers to judge online communication as incapable of conveying subtle relational messages and therefore as an unsatisfactory medium for meaningful interpersonal exchange (Kiesler, Siegel, and McGuire 1984). However, in the intervening years, online skills have improved and online communication norms have evolved, with the result that modern communicators routinely use IRC and other CMC systems to engage in effective and meaningful interaction of all types. Modern researchers generally accept that all of the social norms and cues necessary for meaningful interaction do arise in IRC—or any other CMC medium—but at a slower rate than in face-to-face conversations (Walther 1996).

THE DARK SIDE OF IRC: SECURITY AND LEGAL ISSUES

Hate and Harassment on IRC

The anonymous nature of online communication systems such as IRC may contribute to the use of aggressive or inflammatory verbal abuse in the form of harassment or hate speech. Most IRC interactions involve the use of nicknames only, and users rarely reveal their true identities. This anonymity may contribute to a perception of low accountability, with the result that some IRC users may verbally lash out against individuals or groups in ways that are offensive and illegal. For example, Herring (2002, 2003) documented instances of flagrant sexual harassment on IRC and posited that male-dominated online environments are often hostile to participants whom they perceive to be female.

For American citizens, First Amendment (free speech) privileges extend to IRC interactions, but so do criminal laws preventing hate speech, inciting violence, and stalking. U.S. federal laws expressly forbid cyberstalking and online harassment (Executive Order 13133, Unlawful Conduct Using the Internet), which occur when a user annoys, abuses, threatens, or repeatedly initiates unwanted communication with another. Responsible channel operators seek to eliminate such activity on IRC channels by banning the offending user and, if necessary, reporting the user to legal authorities. Occasionally, however, chansops themselves engage in unethical communication behaviors (Herring 1999, The rhetorical dynamics of gender harassment on-line). IRC communications are subject to surveillance by law enforcement authorities acting pursuant to lawful court orders. IRC service providers, including operators, are required by law to cooperate with law enforcement authorities to effectuate the surveillance. Of course, many IRC participants are not U.S. citizens and not constrained by American laws, pointing to the ethical and legal complexities of global communication networks.

Children and IRC

Although a significant percentage of overall Internet users are under the age of 18, the number of minors on IRC may be relatively smaller. In truth, IRC is not especially suited to the needs and concerns of children, who tend to hang out in other Web-based chat systems that maintain

terms of service, restricting certain activities and topics of discussion. Offenders in these chat rooms can be quickly and effectively removed by administrators. IRC channels, on the other hand, are generally not restricted, and certainly not as well policed. It is not infrequent to encounter adult conversations and offensive language on IRCs that would be unsuitable for children. On moderated channels, chanops can always remove a user's "voice" and disable the offender's ability to contribute to further discourse, but such censorial functions are not characteristic of most IRC channels. IRC is perceived by many to be spontaneous, freewheeling, unrestricted, and unpredictable—a kind of "Wild West" communication context.

In carefully controlled and appropriate IRC channels, children may benefit from online conversation with other children from around the world, with teachers and classmates, and with extended family members or parents who are traveling. In fact, chat systems are a quite common component of many online, educational courses. Unsupervised, however, children on IRCs may encounter risks such as cyberstalking, possibly leading to physical stalking if the child reveals personal information; offensive and harmful conversations with unwholesome characters such as pedophiles; and exposure to sexual content, viruses, or other harmful material, if the child accepts a file transfer from an unknown IRC user. Numerous laws and regulations exist to protect minors on the Internet, and responsible IRC users should immediately report any suspicious activity involving a minor on IRC. Since 1997, the FBI has vigorously investigated and prosecuted online pedophiles and stalkers of children through its "Innocent Images" program. Agents go online and pose as children to attract the attention of these criminals. Once these criminals make their moves on what they think are vulnerable children, they are arrested and brought to justice. The program has already resulted in several hundred convictions.

Scripts and Viruses

Informed IRC users are aware of the many risks involved with file transfers, through both hard media and the Internet. When users install new software, download Web pages, or receive files from external sources through either networking or hard media such as disks or CDs, some degree of security risk is introduced. It is a rare occurrence, but even respected commercial software has been distributed with inadvertent flaws that damage systems. More common is the intentional or unintentional passing of a virus or harmful script from user to user through various Internet connections, including IRC. Responsible users minimize these risks by maintaining awareness of current security threats, practicing discretion when networking, and taking steps to keep applications and operating systems up to date.

Most viruses are in .exe or .ini files, but they can also be concealed in zipped files or embedded in completely unrelated file types such as .jpg or .gif files. When launched by an unsuspecting user, viruses can cause irreparable harm to individual computers and potentially spread throughout entire systems. Some viruses are not destructive but merely irritating, such as those with

pop-up messages of a humorous or salacious nature. Others may disable or destroy hard drives, data files, operating systems, and peripheral components, or create havoc throughout entire networks.

People who share word-processing files, script files, graphics, or other file types on IRC may potentially be spreading viruses, Trojans, or worms. Trojans (or Trojan horses) are spread by users who transfer seemingly benign files containing harmful concealed code. Worms are viruses that propagate themselves and migrate from one application to another within a computer, and from one computer to another within a network.

Scripts represent another source of external control and increased security risk. Scripts are files containing macros (or mini-programs) that enable an application to combine or automate various functions. IRC users have created scripts for tasks such as completing nicknames from typed initials, automatically performing ping operations, generating automated "away" responses, and customizing the output of IRC interactions. Some early IRC users enhanced the function of their IRC clients by writing scripts that have subsequently been incorporated into more recent versions of the software. Within the IRC community, techniques of script-writing constitute a frequent topic of conversation, and the sharing of scripts among users is relatively common. A number of Web sites or FTP download sites serve as archives or clearinghouses for the open sharing of scripts and script paks (sets of coordinated scripts) for various IRC clients. When an IRC user downloads a script file from an archive or another user; however, there is always a risk that the file may contain concealed or deceptive code that may launch unexpected or harmful functions in the receiver's system.

Most IRC clients include options to limit or disable the automatic or unintentional running of scripts, just as the major Web browsers include settings to control scripting functions encountered on the World Wide Web. Because harmful functions can be inserted into otherwise legitimate scripts, cautious IRC users run scripts only after proofreading every line of the code. Safe practice also calls for the careful screening of IRC users before accepting from them any files of any type. Common practice states that files should never be accepted from an unknown person, and file transfers from known parties should always be scanned for viruses before being opened.

Mischief and Sabotage on IRC

Many people use IRC safely and never experience viruses, takeovers, or threats to their security. It is not uncommon, however, to encounter less serious offenses allegedly launched by mischievous youngsters known as "script kiddies." (For a more serious perspective on "script kiddies," see Gilboa 1996.) Anyone who has been on IRC very long has probably observed attempts by an aggressive user to take charge of a channel or disrupt the flow of messages on a channel or network. "Channel taking" may be accomplished if a user is granted chanop status or deceptively uses an operator's nickname, then "de-ops" the other operators and indiscriminately bans users, kicks them off the channel, or silences their

voices by turning the channel into a moderated one. Sometimes malicious users simultaneously send multiple files to another user, known as “flooding.” If practiced on a large scale, flooding can significantly increase lag on a channel or entire network. Most IRC clients include optional settings that limit flooding to that client.

A more serious form of sabotage exists in denial-of-service (DoS) attacks, harmful data packets that sneak through loopholes in an operating system’s security and launch erroneous messages from or to the client. DoS attacks, sometimes called “nukes,” are against the law and can cause the host to disconnect from the Internet, freeze, or crash entirely. IRC can be exploited to facilitate a DoS attack by sending scripts called “bots” to unsuspecting users. Bots use vulnerabilities in the operating system to initiate the attack simultaneously from multiple computers. Engaging in such destructive practices violates federal law, specifically the Computer Fraud and Abuse Act (18 U.S.C. § 1030), as well as many state statutes. As a result of these laws, even first-time offenders could get jail time and stiff fines.

Because internal security is especially critical to certain types of organizations, some companies or institutions have restricted the use of IRC and other Internet functions through the use of firewalls that prohibit any computer in their network from connecting to an IRC server. For any IRC user, whether institutional or private, the best defense against mischief and sabotage is to refuse to accept file transfers or DCC chat requests from unknown persons, to carefully peruse every line of script code before launching it, and to maintain updated security files for operating systems, IRC clients, and virus protection software.

THE FUTURE OF CHAT

Although IRC is no longer as popular as it once was, its legacy lives on in modern chat programs. IRC use may be declining relative to other technologies, but chat as originally defined by IRC remains as popular as ever. There are still many popular Web-based chat programs that are built using IRC protocols and a Web-based IRC client. For example, when ICQ—a popular instant messaging service—added chat services, network administrators ran their own IRC servers to support this interaction. Other services, like MSN Chat, have taken these ideas and interaction style and implemented them using proprietary network protocols, technically distinguishing them from IRC, although they work quite similarly from a user’s perspective.

Although the Internet community has largely moved on from IRC, chat still remains a popular and evolving conversational medium. In both commercial services and the academic research community, new chat interfaces appear frequently (e.g., Churchill et al. 2000; Farnham et al. 2000; Erickson et al. 2002; Smith et al. 2002). In fact, there is an argument to be made that enormously popular instant messaging services—online services that facilitate primarily one-to-one, text-based conversations between Internet users who already know one another—have their foundations in chat and IRC. IRC may have dropped off the radar, but chat is still an exciting area with much potential for future development.

GLOSSARY

Ban: Status of a user forbidden by a chanop to enter a channel.

Channel: A virtual chat group in which users interact, discussing specific topics or engaging in general conversation.

Chanops: Channel operators; they monitor and maintain a channel by setting the parameters and inviting or pelling users.

Client: Software run by the local computer of an IRC participant, converting the user’s actions into commands recognized by an IRC server.

Daemon (IRC daemon, or IRCD): Software run by a server connected to the Internet, accepting connection requests from clients and relaying messages among users.

Direct Client Connection (DCC): Connection established between two users that allows them to bypass the network for increased privacy and faster connection.

Flooding: Simultaneously sending many messages to a single user, thus “flooding” a channel or an entire network with unwanted messages, probably increasing lag.

Internet Relay Chat (IRC): Real-time, text-based communication medium that uses a network of servers to connect geographically separated users.

IRCops: IRC operators who monitor and maintain IRC servers; they generally have very little to do with the operation of channels.

Lag: A delay in the transmission of messages between users or between a user and a server.

MOTD (Message of the Day): An automated confirmation message containing certain information and practices relating to a channel, its activities, and its current participants.

Netsplit: Disruption in the connection between servers that results in the fracturing of the network into subdivided parts and in the disconnection of some users.

Newbie: A newcomer to IRC or other online contexts.

Nickname: An invented name that uniquely identifies the user on a network.

Scripts: Files containing code that enables an application to combine or automate various functions.

INTRODUCTION

The Internet was not invented as a social technology, but it has certainly become one. From the earliest days of the ARPAnet (network of communicating computers established in the late 1960s with U.S. government funding), people have shaped and used the technology for social purposes. Today, millions of people use the Net as a means of making and maintaining social connections with people who share a common experience, interest, or concern. Social connections are found on the Net in contexts ranging from small family e-mail exchanges to fantasy games with hundreds of thousands of players. This chapter focuses on a subset of Net-based social contexts, which in the 1990s came to be called "online communities." In these Net-based social contexts, large numbers of people who share a common experience, interest, or concern interact with one another primarily, if not exclusively, over the Net. Most members have no preexisting ties with one another, and most of them will never meet face to face. Online communities range in technical sophistication from Usenet discussion groups to complex multiplayer fantasy games supported by proprietary software. They range in purpose from entertainment to political dissent to developing free software. They range in accessibility from completely open to anyone with Net access to accessible only through paid subscription to completely hidden behind corporate firewalls.

This chapter describes how technical and social factors mutually interact to produce and sustain online communities. It also begins to offer a differentiated view of online communities. Online communities share some underlying attributes and processes, but they differ in member interests, goals, processes, and consequences for their members, sponsors, and society. A more differentiated view will make possible more productive theorizing, research, and design.

DEFINITION AND COMPONENTS

Definition

Communities in the offline world are defined as collectivities of people who share a common experience, interest,

or conviction; who experience a positive regard for other members; and who contribute to member welfare and collective welfare (Bender 1978; Etzioni and Etzioni 1999; Knoke 1986; Putnam, 2000). Not all social collectivities in the offline world are communities: people may share a common experience or interest, such as shopping at the same grocery store or reading the same newspaper columnist, with no positive regard for others or commitment to the collective welfare of all who share that experience. Examples of communities in the offline world include neighborhood communities, religious communities, civic and social communities such as youth scouting or service clubs, and collections of like-minded enthusiasts such as fans of particular sports teams. Communities in the physical world can be described by structural attributes such as rules, roles, and resources that exist independent of any member (e.g., Lin 2001). Thus, one can talk about the size of a community, membership requirements and obligations, community resources, and amenities. Communities can also be described by observable member behaviors such as attendance, rule following, donation, and interaction. And they can be described by member psychological orientation to the community and its members, such as feelings of trust, alienation, identification, and commitment. In the physical world, structural, behavioral, and psychological attributes exist along a continuum, so one can find more or less well-structured communities with more or less active and committed members. In casual usage, the term *community* usually suggests positive feelings, prosocial behavior, and choice. (People rarely talk about a "prison community," even though its inmates interact and have experiences in common.) Analytically, however, the term is a neutral one. Communities and their members can do physical and economic damage to members, neighbors, and enemies, just as they may produce beneficial outcomes.

The definition of *online community* used in this chapter is also based on shared experience, interest, or conviction; positive regard for members; and members' voluntary contribution to member welfare and collective welfare. An *online community* is defined as a large collectivity of voluntary members whose primary goal is member and collective welfare, whose members share a common

interest, experience, or conviction and positive regard for other members, and who interact with one another and contribute to the collectivity primarily over the Net. Online communities can have more or less structure and more- or less-committed members. They may yield positive or negative consequences for their members, sponsors, and society. It is difficult to tightly bound the concept of community, because all human interaction occurs in a continuum of social organization—from the dyad to the nation-state. Nevertheless, the definition of *electronic community* used in this chapter excludes some forms of organized online social interaction for reasons of focus and because they are deserving of consideration in their own right. Table 1 shows the attributes of organized online interaction that are emphasized or deemphasized in online communities. As shown in Table 1, our definitional focus excludes electronic work groups and teams, whose primary goal is economic, whose members are paid employees, and whose size is relatively small. It excludes ad hoc friendship groups and buddy lists, which are relatively small, with members who interact primarily in the offline world. These two exclusions highlight our focus on shared interest groups of large size with voluntary members who interact primarily on the Net. The definition also excludes nominal groups such as “all the people who use Google” or “all Netizens” (who neither share a common interest nor interact with one another) or “all the people who read a particular Web log” (who may share a

common interest but do not interact with one another). This exclusion highlights our focus on social interaction around a common interest and positive regard for other participants. Others who have offered definitions of electronic communities include Figallo (1998), Kim (2000), Porter (2004), Powazek (2002), Preece (2000), Rheingold (2000), and Werry and Mowbray (2002).

Until the mid-1990s, almost no one used the term *online community*. Instead groups that today might be named “online communities” were named after the technology that supported them and were called “newsgroups,” “list-servs,” “mailing lists,” “BBSs,” or “Free-nets.” In some ways, online communities that are the focus of this chapter bear little resemblance to communities in the physical world. They own few tangible resources; they require no visible or tangible commitment from members (such as taxes, dues, attendance at meetings); and members may never see or meet one another face to face. Yet some online communities have resources that may be economically valuable: their domain name, the wisdom accumulated in their FAQs (frequently asked questions), the intellectual property created by their members. Fantasy game characters and properties have yielded nontrivial sums of money for their creators on eBay auctions. The members of one voluntary online community collected enough money in member donations to buy a new server to host the community (Boczkowski 1999). Nevertheless, calling any electronic site where people may gather an

Table 1: Descriptive Attributes Characterizing Online Social Collectivities

Type	Shared Interest	Size	Interaction among Members	Primarily Electronic	Voluntary Participation	Concern for Member/Collective Well-Being
Corporate electronic work groups	Strong	Small	Extensive	Sometimes	No (part of employment)	Economic well-being of collective
Buddy lists	Modest to strong	Small	Minimal to extensive	Sometimes	Yes	Member, but not collective
People who read a particular blog	Modest to strong	Small to large	Minimal	Yes	Yes	No
People who use Google	None	Large	None	Yes	Yes	None
Social network	Modest to large	Small to large	Minimal to modest	Often	Yes	Rarely
Discussion community	Yes	Large audience; smaller contribution core	Minimal for readers; extensive for posters	Yes	Yes	Varies by level of participation; significant for contribution core
Online collaborative work community	Yes	Large audience; smaller contribution core	Minimal for readers; extensive for contribution core	Yes	Yes	Varies by level of participation; significant for contribution core

Note: Online communities, denoted by shading, are a subset of online social collectivities.

“online community” does not make it one. As in the off-line world, in common parlance the term carries positive connotations, and some who have used it are guilty merely of wishful thinking. This wishful thinking characterizes many of those who, in the late 1990s, aspired to create online communities for profit (e.g., Bressler and Grantham 2000; Hagel and Armstrong 1997).

Supporting Technologies

In addition to the packet-switching technology of networked communication, many online communities rely on message-based group communication applications to support member interaction. These applications generally support asynchronous or synchronous discussion and interaction. In asynchronous interaction, people do not have to be logged on at the same time because messages are saved for later reading. In synchronous discussion, people must be logged on at the same time because messages are not stored. Asynchronous discussion is often supported via mailing lists or bulletin board applications. Mailing lists, a push technology, send group messages to a person's e-mail inbox, where they intermingle with the person's other e-mail and are saved until the recipient logs on to read them. With bulletin boards, a pull technology, a person reads group messages organized by topic in a file exclusively devoted to that group. (Some people establish filters to move all mailing list messages into separate folders, thereby making distribution lists function somewhat more like bulletin boards.) Synchronous discussion may be supported via talk programs such as IRC (Internet relay chat), Instant Messenger, or text-based virtual reality (VR) environments. MUDs (multi-user dungeon, domain, or dimension) and MOOs (MUD object-oriented) began as text-based virtual reality games, a computer-based version of fantasy games such as Dungeons and Dragons. Today, some are still organized as fantasy games; others are organized for professional or social purposes. Their spatial metaphors and programmable objects and characters are the precursor of today's graphically based fantasy games. With the spread of the Web and graphical browsers in the late 1990s, many online communities, which previously would have used only text-based message applications, created Web sites to support more varied forms of interaction. Some include real-time chat for discussions that are scheduled and announced in advance. Some use special file formats to share image, sound, or video files. Online game communities are supported by more or less elaborate software that supports play in board games like chess or supports character creation and interaction in fantasy worlds. Most discussion among members on online community Web sites still occurs in message-based discussions, however. Even the fantasy games have discussion boards.

In the early years of the twenty-first century, technologies for preparing, publishing, and linking Web pages became easier to use and spread widely to support large social collectivities. The “blogosphere” consists of everyone who uses applications for preparing and publishing Web pages to publish a Web log (blog), which consists of an online journal with time-stamped entries displayed in reverse chronological order. The blogosphere is merely a

very large nominal group, and not a community by our definition, but some bloggers who share a common interest in a topic may interact with one another indirectly through commenting on one another's blogs. Much of the “interaction” resembles online journalism or columns with linked letters to the editor, rather than the more interpersonal interaction found in message-based communities. (Nardi and colleagues [2004] identify five broad motivations that drive people to publish a blog, only one of which is related to community formation and maintenance.) However, some groups of blogs may be considered a community by our definition. These topical groups may crystallize in “Web blog rings” created by an application that places a banner at the bottom of related participant blogs; upon clicking on the banner, the reader is taken to another, randomly chosen blog that is a member of that “ring.” Over time, blog-ring members may develop a psychological affiliation with the Web blog ring and interpersonal bonds with one another that go beyond merely posting and reading blog entries on a common topic. (Herring et al. [2004] report that fewer than 5 percent of blogs belong to a blog ring.)

Social networking Web sites allow their members to establish, develop, and maintain “social networks” through publishing and linking “profile” pages created by their members. These are structured Web pages in which members share information about themselves. The “social” nature of these sites essentially results from three features. First, the software allows users to add links to other people's profiles, thereby adding “friends” to one's network. Once in the same network, site members have easy access to one another's profiles through an automatically generated list of “friends” on their home page. Second, users are able both to exchange asynchronous messages among themselves and to “chat” synchronously online. The ability to broadcast a message (called “bulletins” on some of the sites) to all “friends” is also provided, as are “comments,” which can be attached to a member's profile (thus becoming visible to all who visit that profile). Third, these sites typically support “groups,” which members with a common interest or experience can join. This feature allows users to self-organize along lines other than those defined by their preexisting social networks and explore their “extended network” (the term used by one social networking site, MySpace, to characterize members who do *not* belong to a member's list of “friends”) in yet another way. Social networking sites and applications are enormously popular (MySpace was the third most frequently visited Web site during July 2007). But like blogs, most social network sites do not exhibit all of the attributes enumerated in our definition of online community. Although creating a profile is an entirely voluntary act, the ability to join someone else's social network occurs only by invitation. Moreover, the concept of community welfare, a necessary attribute in our definition of online community, is rarely prominent in these sites. One sociologist commented that these sites are characterized by “voyeurism and exhibitionism . . . [like] hanging out at the mall or lounging on the quad . . . seeing and being seen” (Cassidy 2006).

A wiki is a software system that serves Web pages while providing site visitors the possibility to easily add, modify, or delete their contents. At its simplest, wikis merely

generate HTML code that includes discrete links labeled “edit” interspersed along the page. If a user follows such a link, she will be presented with a form that allows her to edit the contents of the page that she was previously reading. The page is edited using a simple markup language; modern wiki implementations also provide a set of buttons through which the same functions (e.g., italicize text, create a hyperlink, etc.) can be accomplished without knowledge of that markup language. Either way, once a modification is done it is immediately reflected in the original page. The fundamental change introduced by the use of a wiki in comparison with traditional Web sites is that the authors and readers of a site are no longer two distinct groups: instead, active participant visitors can create and directly edit the content that attracts those same visitors to the site. Wikis are successfully used both by large online communities—the best-known example being Wikipedia (<http://en.wikipedia.org>), a collaborative effort to create an online encyclopedia; the English edition contained 1.9 million entries as of July 2007—as well as by work groups within organizations.

General Attributes and Processes

The Social Psychology of Text-Based Communication

Typically, online community members interact with one another while sitting alone at a computer keyboard. This solitary social behavior is characterized by fewer social context cues than are available in face-to-face gatherings. Weak social context cues mean that people who compose and send messages have few explicit reminders of the number of people who will read them. They have few reminders of their physical appearance, social status, or nonverbal reactions compared with face-to-face or telephone communication. Similarly, people who read messages or Web pages have relatively few reminders of the social attributes of people who create them in comparison with face-to-face gatherings. (In virtual reality communities, people can create entirely new personas. See Turkle [1995] for an exploration of multiple online identities.) Social context cues help to regulate communication in face-to-face and telephonic interaction. They provide feedback as to who is receiving communications and how those communications are being received and interpreted. People adjust the style and substance of their communications as a function of these cues. When those cues are attenuated, communication tends to be relatively frank and open (Kendall 2002; Reid 1999; Sproull and Kiesler 1991). Weak social context cues can lead to different effects, even within the same community. They can increase affiliation and commitment among members because objective differences among members are obscured while subjective similarities, based on members’ common interest, are magnified (Galegher, Sproull, and Kiesler 1998; Mackenna and Bargh 1998; Sproull and Faraj 1995). Alternatively, they can increase disaffection and dropout because it may be more difficult to establish common ground or consensus and manage conflict (Carnevale and Probst 1997; Cramton 2001; Dibble 1998; Herring 1994; Kollock and Smith 1996). Weak social context cues condition communication in many online communities. They allow for a potentially greater geographic

and social diversity of participants than many physical communities do. At the same time, they offer few cues to that social diversity in interaction, except those revealed through language and linguistic cues (e.g., Herring 2001). Increasingly, Web-based community applications encourage members to upload profile files, which can display enduring personal information about members’ identities and interests. Still, in 2007 most interaction among community members takes place via text messages in the absence of other individuating information.

Microcontributions

Many of the tools for electronic community participation are based on a relatively fine granularity of time and attention—the text message, the blog entry, the page edit. Although contributions can be any length, messages sent to asynchronous discussion communities typically range between ten and thirty lines, or one to two screens, of text. For example, Winzelberg (1997) reported a mean of 131 words; Galegher et al. (1998) reported a mean of eight to twenty lines of new text; Wasko and Faraj (2000) reported a mean of twenty-five to thirty lines of text; Sproull and Faraj (1995) reported a mean of twenty-two to forty-two lines of new text. The average blog entry, according to Herring et al. (2004), has a length of approximately 210 words. Wikipedia articles on average run to 415 words (Wikipedia: Size comparisons 2006). In asynchronous applications, people can read one or more messages or pages and post or send one or more messages/pages at their convenience. The message can be thought of as a microcontribution to the community. When people are online much of the day as a part of their work, voluntary microcontributions can be interspersed throughout the work day. For those who have Net access at home, participation can also be interspersed with other activities at home. Even in synchronous communities, some members report that they keep a community window open on their screen while they are doing other things. Every once in a while they “check in” on the community (Kendall 2002). Some people may devote hours a week to an online community, but they can do so in small units of time at their own convenience.

Voluntary communities based on microcontributions have relatively low barriers to entry. It is fairly easy to read enough microcontributions to know whether a particular community is relevant or appropriate. If so, that same reading readily demonstrates the appropriate form that a newcomer’s own microcontributions should take. The production and posting of initial microcontributions takes relatively little effort. Then, if all goes well, the newcomer receives positive reinforcement in the form of (easy-to-produce) responding microcontributions from other community members. Whereas microcontributions create low barriers to entry, they may also create high barriers to commitment. It can be difficult to develop complex arguments or achieve nuanced understanding through microcontributions. Communities that are easy to join are often just as easy to leave (Butler 2001).

Aggregation Mechanisms and Management Processes

Although people can make ad hoc contributions to online communities at random, microcontributions must be

aggregated and organized into larger units for efficiency and social effectiveness. Both technical and social mechanisms are used to organize the smallest unit of contribution into larger units that are useful to participants. Software for asynchronous discussion lets people indicate that their contribution is a response to a previous one. All contributions so designated can be aggregated by the software and displayed as “threads”—a seed message and all reactions to it. Forms of threads common from the earliest days of the Net include a question with replies and a proposal or statement with comments. Threads organize microcontributions so that everyone can see their constituent parts, making it easy for potential contributors and beneficiaries to see what has already been said. Software also allows readers to mark threads they have already read or to display only unread messages.

Asynchronous discussion communities may have tens or hundreds of threads active at the same time, necessitating a layer of organization above the self-organizing thread. In these cases, a human designer may suggest or impose a topic map or architecture to organize threads into more general topic categories. (In some older bulletin board systems, people would vote to create a new top-level topic, which would get its own separate bulletin board.) Web-based software can display these maps graphically so that users may click on a topic that interests them and see all threads related to that topic. The shared interest of a group usually suggests the type of topical map that may be created. For example, many communities centered on medical concern have topics for symptoms, medications and side effects, negotiating the health care system, and managing relationships with family and friends. Movie or television fan communities have topics for major and minor characters, actors who play those characters, past and future episodes. Communities that build software have categories for different types of code, bug reports, patches, and documentation.

Threads and topic maps may be insufficient to structure extremely large numbers of messages. Another form of microcontribution, the rating message, adds a quality dimension to message structuring. Some Web sites now give members the opportunity to rate the contribution of others' messages. Software then aggregates and displays these ratings in an overall quality index for contributions (e.g., Slashdot) or contributors (e.g., MotleyFool). Explicit ratings of contribution quality have been shown to increase economic trust within electronic markets like eBay (Kollock 1999). It is an open question whether they increase or inhibit emotional trust and cohesiveness within an electronic community setting, but at least some research suggests that they increase the average quality of messages and increase participant duration (Moon and Sproull 2006).

Software for synchronous interaction may organize contributions in channels or use a spatial metaphor to organize contributions in “rooms” (e.g., Schlager and Schank 1997). Online communities associated with a geographic locality may organize contributions around civic functions, like the garden club or public library (e.g., Sproull and Patterson 2004). As these communities increase in size, the organizers or members themselves construct new rooms, buildings, and territories to organize

interaction. Some also offer rating and review functions to rate characters or contestants and properties.

In online software development communities, two technologies, in addition to mailing lists, support managing and aggregating contributions: revision control systems and a “diffing and patching” mechanism. Revision control systems allow developers to work independently on code in parallel and then automatically “merge” all the changes they have made, so that the result is a single, consolidated version of the code. Core developers and regular contributors will be granted “write-access,” meaning that their account in the revision-control system allows them to introduce changes to the code (as opposed to only being able to download it). Those who lack write-access to the code repository download the latest version of the code, modify it, and then present the changes they introduced to one of the core developers for acceptance. They do so by running a program called “diff,” which generates a small file describing the changes between two versions of one or more files. These small files are called “patches.” The core developer who receives a “patch” can then use a second program (itself called “patch”) to obtain the modified version of the code and determine whether it should be added to the code base.

Most wiki systems include several additional organizing features with the aim of addressing difficulties arising from disagreement over the site's contents and the risk of “wiki vandalism.” First, each page on the wiki has an associated “talk page,” where contributors can engage in a discussion of the changes they have introduced (or wish to introduce) on that particular page. Second, the system includes a “page history” function, through which participants can see a log of all changes introduced to a particular page. Most importantly, that same mechanism allows pages to be easily “reverted” to a previous state; it is through this mechanism that “edit wars”—in which groups with different views on an issue repeatedly try to modify the wiki's contents so that it reflects a particular group's perspective—take place. Third, and although it is often seen as being in contradiction with the democratic ideals of the wiki system, several platforms also allow the administrator(s) of the wiki to restrict the ability to introduce changes to certain pages. A well-known instance is that of Wikipedia and its several levels of protection: some pages can be edited by any visitor; others require an account on the Wikipedia Web site that is at least 4 days old but is otherwise unrestricted; and, finally, some other pages can be edited only by Wikipedia administrators.

Norms and Motivations

In addition to organizing mechanisms provided through software, norms of community behavior and motivations of community members serve to organize and influence member behavior. Some norms of community behavior, which were visible from the early days of the ARPAnet, prevail across many types of online communities. Most important is the norm of altruism. Online community members freely offer information, advice, and emotional support to one another with no expectation of direct reciprocity or financial reward. The fundamental dynamic supporting discussion communities is that someone asks a question or makes a proposal or statement and other

people provide answers or comments. Utilitarian self-interest may be all that motivates the askers—a personal need for information. But pure self-interest does not explain the behavior of people who reply. By definition, volunteer members are not paid for their replies. Because they are unlikely to have a personal relationship with the person they help, neither friendship obligation nor the expectation of direct reciprocity is likely to compel their behavior. Indeed, an early influential paper (Thorn and Connolly 1987) predicted that computer-based information exchange systems that relied on volunteers would be doomed to failure. The authors argued that people who could give the best replies would have no incentive to participate because they would receive few benefits for doing so—it was unlikely that anyone could answer their questions; their time would be unrewarded. (In social dilemmas, helping in these situations is known as the “sucker’s choice.”) Over time, therefore, the quality of help would decline until people no longer even bothered to ask questions. The fallacy in this argument is the assumption that rewards to people who provide help must come in the same form as the help they give. Yet motivations for helping behavior can be quite complex. In studies of volunteers in the physical world, motivations include commitment to the cause or interest associated with the community, the desire to help others, benefits from displaying expertise, and the personal satisfaction and self-esteem derived from helping others (e.g., Clary et al. 1998; Omoto and Snyder 1995). Studies of electronic discussion communities document a similar combination of motivations for people who answer questions and otherwise support their online community (e.g., Butler et al. 2007; Kollock 1998; Lakhani and von Hippel 2003; Wasko and Faraj 2000). Self-expression and identity display are important motives in blogs and social networking sites.

A second extraordinarily important norm is peer review of content (Benkler 2002). In most volunteer online communities, there are no “authorities” to certify the accuracy of all content. Instead, it is expected that members themselves will comment on the quality, accuracy, completeness, and so on of one another’s contributions. Similarly, peer review of behavior is also expected: it is normative for members to chastise or complain about inappropriate behavior and praise helpful behavior.

In virtual reality communities, the VR environment indexes participants’ motives (Reid 1999). In VR game communities, the motives are tied to the rules of the game: amass property, kill enemies, design an award-winning room, and so on. In VR professional communities, the motives are tied to the profession: contribute to shared databases, review articles, participate in policy discussions. In VR social communities, the motives are tied to exploring social worlds. In collaborative work communities motives are tied, at least in part, to furthering the goals of the community such as building better software, distributing digital books, organizing volunteers, etc.

HISTORY OF ONLINE COMMUNITIES

Both the technical and social trajectories of electronic communities began with the design and early deployment of networked computing in the late 1960s and early

1970s. (See Table 2 for timeline.) Whereas computer networking was initially conceived as a way to share scarce computing resources located in one physical place with researchers at other places via remote access, it soon became a convenient way for people to gain access to people at remote sites as well as to remote computers (Licklider and Veza 1978; Sproull and Kiesler 1991). During the 1970s and 1980s, people created additional networks and wrote e-mail and bulletin board software, which represented technical innovations and improvements that made networked computing more useful for supporting human communication. During the 1990s, the technical innovations of the Web and the graphical browser supported the broad diffusion of electronic communication to millions of U.S. households and hundreds of millions of people worldwide. In the first years of the twenty-first century, easy personal publishing and page linking undergirded an explosive growth in social networking and blogging.

The social trajectory of electronic discussion communities had its beginnings in the same technical community that invented and refined the ARPAnet. By the mid-1970s, ARPA program officers and researchers around the country had begun using group e-mail to share results, discuss plans, and organize meetings. Some of these researchers also began using group e-mail for purposes unrelated to work: for example, to share opinions on cheap Chinese restaurants in Boston and Palo Alto, favorite science fiction books, inexpensive wine, and new movies. This research community invented both the technology (networking and group communication tools) and the new form of social organization (the voluntary electronic group). They appropriated technologies that were created for utilitarian purposes to create self-organizing forums for the voluntary discussion of common interests. The social trajectory of VR communities began in 1979–1980 with an effort to program a game that would be like the fantasy game *Dungeons and Dragons* that was played in the physical world. The first multi-user VR game was accessible on the ARPAnet in 1980.

By the twenty-fifth anniversary of the ARPAnet in 1994, electronic group communication had become a taken-for-granted process, and voluntary electronic discussion communities had become a taken-for-granted organizational form in universities, technical communities and scientific disciplines, and some corporations (e.g., Finholt and Sproull 1990; Kiesler and Sproull 1987; Orlikowski and Yates 1994; Walsh and Bayma 1996). Multiplayer games were also becoming popular on university campuses. Despite their growth, at this point both discussion groups and games were still in large measure the province of young, technically adept men. The final years of the twentieth century saw Net-based communication enter the mainstream of U.S. life because of a combination of technical and economic developments. The technical developments were the Web and the graphical browser, which made it much easier for ordinary people to find and access information and groups on the Net. The economic developments were the commercialization of the Net and AOL’s business model. Once the Net began to be commercialized, corporations began to see potential economic value in electronic communities and so endeavored to support them

Table 2: Timeline for Community-Oriented Group Communication on the Net

Date	Name	Technical Developments	Social Developments
1965–1968	ARPA projects	Research on networking to share scarce computing resources	Networking research community forms across small number of labs
1969	ARPAnet	First four ARPA sites connected	
1972	RD	First ARPAnet e-mail management program	
1973			75 percent of ARPAnet traffic is e-mail
1975	MsgGroup	First ARPAnet mailing list	
1978	BBS	First bulletin board system	
1979	Usenet	Free software to share bulletin board discussions	
1979	MUD	First multiuser VR game	
1979	CompuServe	Began offering e-mail to customers	
1980	MUD	MUD first played over ARPAnet	
1981	Bitnet	Computer network for non-ARPAnet universities	University computer center directors band together to support this
1981	Sendmail	Free software to send mail across networks	
1984–1985	Delphi, Prodigy, AOL	Commercial information services founded that offered e-mail	
1985	Listserv	Free software to manage e-mail lists	
1986	IETF		Volunteers focused on technical operation and evolution of Internet
1988			>1000 public listservs
1990			>1000 Usenet groups; >4000 posts per day
1990	World Wide Web	Invented by Tim Berners-Lee	
1990	LambdaMOO	VR environment created at Xerox PARC	
1991	Linux	Free computer operating system	First message about Linux posted to Usenet group
1992	AOL	Connects to Internet	
1994	Netscape	Introduced graphical Web browser	
1994			>10,000 Usenet groups; >78,000 posts per day; estimated 3.8 million subscribers to commercial online services
1995	wiki	Software that allows for collaborative writing and editing of Web pages	
1999	blog	Term coined as contraction of “Web log,” Web page journal with timestamped entries	
2000			34 million AOL subscribers; 44 million U.S. households online
2001			90,000 Usenet groups; 54,000 public Listserv groups
2001	Wikipedia		Anyone can create and edit an encyclopedia article on any topic
2002	Friendster	Social networking site founded	
2004			65 percent of U.S. citizens are online; 600 million people worldwide are online
July 2006			MySpace was most visited domain on the Internet; 1.3 million Wikipedia articles published; 97 million Americans use the Internet on an average day

IETF = Internet Engineering Task Force; MUD = multi-user dungeon, domain, or dimension; VR = virtual reality.

and, indeed, to “monetize” them (e.g., Hagel and Armstrong 1997). The commercial online game industry began to grow. AOL’s business model emphasized e-mail and member discussion forums, in contrast with that of other commercial services that were still emphasizing access to databases. By 2000, AOL had 34 million members—more than all the other commercial services combined—many of them participating in electronic forums and communities of interest. That year, 44 million U.S. households were on the Net. (By 2004, nearly two-thirds of Americans were online [Fallows 2004].) Despite the enormous influx of people very different from the ARPAnet pioneers, four themes evident from the earliest days of the ARPAnet continued to characterize electronic communication at the beginning of the twenty-first century: access to people as much as to databases, group communication as well as dyadic communication, personal interest topics as well as utilitarian ones, and self-organizing voluntary electronic communities.

TYPES OF ONLINE COMMUNITIES

Until the early 1990s, most electronic communities used similar technology and their members had similar attributes. Highly educated, young, technically adept people congregated electronically with similar others who shared similar interests. These congregations were relatively homogeneous in structure, process, and membership. At the beginning of the twenty-first century, however, the diversity of Internet users and group goals and processes is so great that it is helpful to differentiate types of communities to understand their costs and benefits in more detail. This section categorizes and describes types of online communities based on the interests that members or sponsors have in common. (See Table 3 for examples.) It is neither an exhaustive nor a mutually exclusive characterization, but it does represent some prevalent types. Despite the differences across types of shared interest, all of these communities are characterized by any-time, any-place

Table 3: Examples of Online Communities

Consumer Communities	
www.audifans.com	Fans of the Audi marque
www.lugnet.com	Adult fans of Lego
www.Britney-Spears-portal.com	Fans of Britney Spears
http://Rec.arts.tv.soaps	Soap opera fans
(A)vocation Communities	
www.mastersrowing.org	For masters rowers and scullers
www.bikeforums.net	For the avid cyclist
www.Everquest.com	For EverQuest players
http://secondlife.com	Virtual reality world built and occupied by its inhabitants
www.chessclub.com	For chess fans
www.tappedin.sri.com	For K–12 teachers and teacher educators
www.LambdaMoo.info/	Virtual reality environment for social interaction
http://boogaj.typepad.com/knitting_blogs/	Knitting blogs Web ring
Place-Based Communities	
www.bev.net	Blacksburg Electronic Village
www.guerrillagardening.org	Volunteers who stealthily plant shrubs and flowers in London
http://web.mit.edu/knh/www/downloads/khampton01.pdf	Wired suburb of Toronto, Canada
www.backfence.com	“Do it yourself local news”
Condition Communities	
www.seniornet.org	For people over age 50
www.systers.org	For female computer scientists
www.deja.com/group/alt.support.depression	Usenet group for sufferers of depression
www.geocities.com/heartland/prairie/4727/bhnew.htm	Mailing list for people with hearing loss
www.deja.com/group/rec.soc.argentina	Mailing list for Argentinian expatriates

Concern Communities	
www.clearwisdom.net	For practitioners of Falun Gong
www.419legal.org	For Internet antifraud activists
www.dailykos.com	Daily political news and commentary with a liberal perspective
www.moveon.org	For online political activists
www.deja.com/group/talk.guns	Usenet group for handgun advocates
www.deja.com/group/soc.religion.mormon	Usenet group for believers in Mormonism
Collaborative Work Communities	
http://vger.kernel.org/	Mailing list for developing the Linux kernel
www.wikipedia.com	Collaborative project to produce an online encyclopedia
www.ietf.org	For maintaining and improving the Internet
www.rhizome.org	For creating and discussing new media art
www.pgdp.net	For digitizing public domain books
www.OhmyNews.com	Online newspaper with contributions by "citizen reporters"

communication with relatively weak social context cues, aggregated microcontributions, and norms of interaction. The boundaries across types can be fuzzy; the descriptions indicate central tendencies within types.

Types by Member Interest

Consumer Communities: Brands and Fans

Consumer communities are composed of people who share a common interest in and are loyal to a particular brand, team, entertainer, or media property. Although people organized fan clubs prior to the Net, it was difficult to arrange fan club activities on a large scale and frequent basis. Online customer communities have a much broader reach. People voluntarily share their information and passion with thousands or hundreds of thousands of others who share their interests in a particular product, entertainer, or media property. AudiFans, for example, is composed of more than 1000 Audi enthusiasts who exchange information about parts suppliers and mechanics, post photos of their cars, and share the joys and sorrows of Audi ownership. The Britney Spears portal contains pictures, MP3 files, news, and forums where thousands of people comment (positively or negatively) on all things having to do with Britney. For most members of consumer communities, the shared interest may be an intense one, but it typically represents a fairly small and often short-lived portion of members' lives.

(A)vocation Communities

Experts and enthusiasts form and join voluntary (a)vocation communities to increase their pleasure and proficiency in their hobbies or work. Whereas a particular product may be a means to advancing a common interest in an (a)vocation community, the product is not the primary focus of attention, as it is in a consumer community. From bicycling to computer programming, dog

training to quilting, karate to the Civil War, there are on-line communities for people who share these interests. "How-to" information prevails in (a)vocation community discussions; members who share their expertise are greatly appreciated. Network and Internet security are a topic for some (a)vocation communities. Usenet, for example, supports more than twenty-five groups on the topics of cracking, hacking, and network security where people discuss how to make or break secure systems. BikeForums, for example, has more than 3500 members who discuss and debate bicycle commuting, mountain biking, tandem biking, racing, training, and so on. The knitters web blog ring connects more than 900 authors of blogs about knitting. Tapped In is a professional VR community for K-12 educators whose 20,000 members, as of 2006, discuss curriculum, share lesson plans, and so on. The Internet Chess Club had more than 30,000 members in 2006 who play chess with other members, take lessons, play in tournaments, watch and discuss grandmaster competitions, and so on. EverQuest and Ultima are large online communities for people who delight in fantasy games. Second Life is a virtual world with more than 2 million inhabitants. The shared community interest in (a)vocation communities may represent a relatively enduring part of members' lives.

Place-Based Communities

These online communities are organized by and for people who live in a particular geographic locale. Their genesis in the early 1980s had a political agenda—to give residents a(n electronic) voice in the local political process (e.g., Schuler 1996; Schuler and Day 2004). More recent versions, such as Backfence, have had the broader goal of building social capital by increasing the density of electronic social connections among residents of physical communities (Hampton and Wellman 1999; Kavanaugh 2003; Sproull and Patterson 2004). In principle, the

interest shared by place-based community members should last at least as long as people reside in the community. (Recent developments like MeetUp.com let people use the Internet to find others in their geographic area who share a common interest for the purpose of scheduling face-to-face meetings. These applications are not emphasized in this chapter because they focus primarily on arranging face-to-face meetings, not on sustaining broader electronic participation.)

Common Condition Communities

In these communities, people share the experience of, and interest in, a common condition. The condition may be based on a demographic characteristic such as race, age, or ethnic background; a medical or psychological condition such as arthritis or depression; or being an alumnus/a of a particular organization such as a college or branch of the military. People join condition communities to learn how others experience or are coping with their condition and to share their own experiences. Along with practical information and advice, a “you are not alone” sentiment prevails in many discussions. BeyondHearing, for example, has more than 1000 members who have a hearing loss or who have a loved one with a hearing loss. Topics range from cochlear implants to the best audiologists to funny stories about lip reading mistakes. Syssters’ membership is more than 2300 female computer scientists and engineers, as of 2006, who discuss female-friendly graduate schools and employers, how to manage male subordinates in the workplace, and so on. The shared community interest is often a long-term or lifetime one for members.

Concern Communities

In these communities, members share an interest in a common political, social, or ideological concern. Because members often wish to influence the state of affairs in the physical world, these communities usually have multifaceted ties to that world. They may announce and comment on real-world events and organize letter-writing campaigns, rallies, fund-raisers, and so forth. They may use click-and-donate applications to raise money or pledges of volunteer time. MoveOn, for example, began as an online petition drive to censure, but not impeach, U.S. President Bill Clinton and has grown to include many online advocacy groups that organize volunteer campaigns. The Howard Dean presidential candidacy used the Net for organizing in 2003–2004. More than 1000 members of alt.religion.mormon discuss and debate Mormon doctrine and practices. A number of blogs support concern communities, particular political concern communities (e.g., Dailykos supports Democratic and liberal/progressive policies and politicians). The shared interest underlying concern communities is likely to be a deep and abiding one for their members, although active participation may ebb and flow in concert with external events.

Collaborative Work Communities

Unlike other community types whose primary output is talk or self-expression, members of collaborative work communities use the Net to voluntarily produce real products, be they software, literary works, or other creations.

Much open source software is produced in online voluntary communities today, despite the growing interest of the corporate sector (e.g., Raymond 1999). Indeed, much of the design and engineering of the Internet itself is accomplished by a voluntary community that conducts much of its business electronically, the Internet Engineering Task Force (n.d.). “Citizen journalists” contribute stories to an international online newspaper. Poets participate in writers’ communities whose members thoroughly critique one another’s work. A pragmatic writing community, Wikipedia, is creating a new encyclopedia. The community project has produced more than 1.7 million English language articles as of July 2007. The distributed proofreaders project has digitized, proofread, and posted more than 5000 public domain books. The shared interest of collaborative work communities is likely to be deeply involving for members, although it need not be as enduring as the shared interest in concern communities.

Types by Sponsor Interest

Only within the past 10 years have online communities been sponsored or organized by anyone other than members themselves (with a few exceptions such as The Well and geographically based bulletin board systems called Free-nets). Many recent third-party sponsors or organizers have been motivated by the profit potential of online communities, with revenue models based on either sales (of advertising, membership lists, products, etc.) or subscriptions. During the dot-com boom, third-party sponsors of some customer and demographic condition communities used sales-based revenue models. Profit-oriented community sites were created for, for example, Leggs panty hose, Kraft food products, women (iVillage), Asian Americans (Asia Street), and African Americans (NetNoir). Some third-party-sponsored communities based on subscriptions experienced some years of economic health; arguably a substantial (but unknown) fraction of AOL’s growth in the 1990s was a function of online community memberships. (In 2006 AOL abandoned its subscription-based model.) Within the game industry, subscription-based revenue models continue to be successful. Several multiplayer game communities have thousands or hundreds of thousands of members. Members of one game, EverQuest, report spending an average of more than 22 hours a week playing it (Yee 2001). At least one professional social networking site, LinkedIn, reports profitability based on subscription revenue. Other social networking sites, based on advertising revenues, do not disclose their financials. But one such site, MySpace, was purchased by News Corp. in 2005 for \$580 million.

Some corporations have avoided revenue-based models and instead have supported online communities to build market share or increase customer satisfaction and loyalty. Sun Microsystems sponsors the Java Developer Connection, an (a)vocation community designed to support and expand the Java software developer community worldwide. The Lego Corporation supports several “adult-fans-of-Lego” sites, in addition to sponsoring its own site, to support loyal customers. Various software companies support voluntary technical discussion and support communities in the interest of increasing high-quality,

inexpensive tech support. Harley-Davidson uses H.O.G., its online members-only group, to reinforce the brand loyalty of Harley owners worldwide. Whatever the motivation of corporate sponsors, if people do not experience enduring community membership benefits they will not participate, and the community will die.

In the not-for-profit sector, foundations and service organizations have sponsored communities for their target populations with the goal of improving their well-being. For example, the Markle Foundation sponsored the creation of Senionet, a not-for-profit online community for people over age 50, which currently has 39,000 members. The National Science Foundation sponsored Tapped In, a not-for-profit online community for K–12 school teachers and teacher educators, which currently has more than 20,000 members.

CONSEQUENCES OF ONLINE COMMUNITIES

Positive Effects

Benefits to Members

Not surprisingly, most studies of online communities report that information benefits are important to their members (e.g., Baym 1999; Lakhani and von Hippel 2003; Wasko and Faraj 2000). What is noteworthy is the form that the information takes. It is not the disembodied, depersonalized information that can be found in databases or official documents, which are themselves easily accessible on the Web. Instead, it is often profoundly *personalized* information. Its form and content are personal—personal experiences and thoughts—whether they take the form of reflections published on blogs, profiles on social network sites, or posts on discussion sites. Likewise, its audience is personal. Questions or requests for comment do not look like database queries: They are framed for human understanding and response. (A discourse analysis of Usenet groups found that almost all questions included a specific reference to readers; the few that did not were much less likely to receive replies; Galegher et al. 1998.) Replies typically address the person or situation engendering the request and are based on the repplier's own situation or experience. In consumer communities, personalized information can increase members' pleasure in using or experiencing the product or property. Personalized information can increase members' pleasure or competence in practicing their (a)vocation. It can also challenge one's assumptions and beliefs (e.g., Kendall 2002).

Members derive more than information benefits from online communities, however. Some also derive the social and emotional benefits that can come from interacting with other people: getting to know them, building relationships, making friends, having fun (e.g., Baym 1999; Butler et al. 2007; Cummings, Sproull, and Kiesler 2002; Kendall 2002; Quan y Hasse et al. 2002; Rheingold, 2000). Of course social benefits are the primary benefit of social networking sites. Occasionally these social benefits are strong enough that they lead some members to organize ancillary face-to-face group activities, such as parties, rallies, show and tell, reunions, or meetings at conferences or shows.

Members of medical and emotional condition communities may derive actual health benefits from their participation in addition to information and socio-emotional benefits. The evidentiary base for these benefits is small, but it comes from carefully designed studies that use either random assignment or statistical procedures to control for other factors that could influence health status. Reported benefits for active participants include shorter hospital stays (Gray et al. 2000), a decrease in pain and disability (Lorig et al. 2002), greater support seeking (Mickelson 1997), a decrease in social isolation (Galegher et al. 1998), and an increase in self-efficacy and psychological well-being (Cummings et al. 2002; Mackenna and Bargh 1998).

Membership benefits do not accrue equally to all members of online communities. Passive members—those who only read messages—may derive the least benefit. This observation is consonant with research on groups and communities in the offline world that finds that the most active participants derive the most benefit and satisfaction from their participation (e.g., Callero, Howard, and Piliavin 1987; Omoto and Snyder 1995). Most studies of online communities investigate only active participants because they use the e-mail addresses of posters to identify their research population; they have no way of identifying or systematically studying people who never post but only read. The few studies that have investigated passive members systematically find that they report mostly information benefits; their total level of benefits is lower than that for more active participants; and they are more likely to drop out (Butler et al. 2007; Cummings et al. 2002; Nonnecke and Preece 2000).

Among active participants, people who participate more extensively report having a greater sense of online community (Kavanaugh 2003; Quan y Hasse et al. 2002). More frequent seekers of information report receiving more helpful replies than less frequent seekers (Lakhani and von Hippel 2003). More frequent providers of information report greater social benefits, pleasure in helping others, and pleasure in advancing the cause of the community (Butler et al. 2007).

Benefits to Third Parties

Many attempts to directly “monetize” online communities through sales revenue from advertising or commerce have been relatively disappointing (Cothrel 2001; Figallo 1998; Sacharow 2000). Although the potential customer base could be quite large for brand or demographic communities, attracting and retaining customer/members is difficult. By contrast, subscription revenues—in the online game industry at least—have been relatively robust, with \$2 billion in subscription revenue reported in 2005 (DFC Intelligence 2006).

In consumer communities and (a)vocation communities, substantial nonrevenue benefits may accrue to corporations through reinforcing customer brand loyalty, increasing customer satisfaction, and even generating input to new product development. Voluntary personal testimonials about a product or experience in the context of giving help can be quite persuasive, both to the person who asked for help or comment and to others reading the exchange. Motivational theories of attitude

formation (e.g., Festinger, Schachter, and Back 1950) and information-processing theories of decision making (e.g., Nisbett and Ross 1980) both point to the influential nature of voluntary personal testimonials. The process can be so powerful that there have been unsubstantiated reports of paid shills masquerading as community members in consumer communities (Mayzlin 2001), a practice known as “astroturfing.”

Much of the help offered in consumer communities and (a)vocational communities is personalized customer support—and potentially quite high-quality support at that. In the software industry, online communities have been recognized as the Best Technical Support Organization of the Year for 1997 and 1999 (Foster 1999). Information that solves customer problems or enhances their product experience is likely to increase customer satisfaction and loyalty. When it is provided by self-organized volunteers, the corporate cost is minimal and the benefits are substantial.

Some online communities offer potential product-development benefits. Most remarked are probably open source software communities that have generated product revenues for companies like Red Hat and product enhancements for companies like IBM and Sun Microsystems. Some game and hobby communities offer extensive product testing before widespread product release (e.g., Wallich 2001). Some actively propose, design, and discuss new product features (von Hippel and Krogh 2003; Jeppesen and Frederiksen 2006).

The strategic question for corporations today centers on what type of corporate involvement in online communities is likely to bring the greatest benefit. With few, but important, exceptions, direct corporate ownership and control of online communities is unlikely to be the answer. (This is not to say that corporations will not benefit from Web-based sales and customer support; e-commerce can be profitable even if online community revenue models are not likely to be.) Forging positive and productive relationships with independent online communities can be challenging, however. (See, for example, Moon and Sproull 2006.)

Benefits to Society

Rigorous empirical evidence is almost nonexistent for online community benefits to society. If members of communities formed around medical conditions achieve improved health status, the cost of their medical care to themselves and society could decrease. Alternatively, better informed members may seek out additional tests or treatments, thereby increasing the cost of their care. If members of targeted populations such as K–12 schoolteachers or senior citizens derive cognitive, social, and emotional benefits from participating in online communities, then the larger society may benefit as well. Data from Blacksburg Electronic Village suggests that participation in online community activities can increase offline civic involvement (Kavanaugh 2003). If members of online concern communities can more effectively mobilize, then the causes served by their advocacy are likely to benefit (e.g., Gurak 1997; Quan y Hasse et al. 2002). Note, however, that online communities can advocate for harmful causes just as easily as they can for helpful ones.

Negative Effects

Although anecdotes are widespread, systematic evidence on the negative consequences of online communities is sparse. Members can be harmed by erroneous, malicious, or destructive information. In social networking sites, lighthearted or unthinking profile information can later be used by potential employers as a reason not to hire someone. The norm of peer review of content in discussion communities acts as a damper on harm from erroneous or destructive information but cannot prevent it entirely. Assessments of the quality of information in online communities are difficult to produce; one study reported that the error rate in Wikipedia articles on scientific topics was essentially indistinguishable from that in the *Encyclopedia Britannica* (Giles 2005). Beyond information-based problems, individual members can be harmed by unhealthy, dangerous relationships that can form via online communities. Unscrupulous or criminal intent can be masked by an online persona that inspires trust and friendship within the community context. If a relationship moves away from community scrutiny and into private e-mail, it can lead to emotional harm, economic damage, or even physical danger. This is a particular concern when predators use online communities to identify and contact minors (e.g., Eichenwald 2006). In social networking sites such as MySpace, young people may be particularly vulnerable because of the disconnect between the perceived experience of “hanging out with friends” and the actuality of loose or nonexistent access controls that allow anyone to view profiles and contact their owners. Within VR communities, there have been a small number of widely publicized “attacks” that caused emotional harm to their members (Dibbell 1998; Schwartz 2001). A group itself can harm its members: cults can exist in cyberspace as well as in the offline world. One such, Pro-Ana, extols the joys and personal freedom of anorexia. Its members share tips on how to hide weight loss from family and friends, discuss the value of personal choice, and praise members’ announcements of their weight loss.

Although participating in an online community may not be directly harmful to its members, involved members may withdraw from their relationships and responsibilities in the offline world. People who spend a great deal of time online must be spending less time doing something else. The research thus far has only examined the effects of aggregate number of hours spent online, not the effects of time spent specifically in online communities. One study found that the number of hours spent online was associated with a small decrease in social involvement and psychological well-being for a particular group of new users (Kraut et al. 1998), but that effect was erased with continued use (Kraut et al. 2002). Some studies have found the number of hours spent online to be associated with an expanded social circle in the physical world (Katz and Apsden 1997; Quan y Hasse et al. 2002; Kraut et al. 2002).

Just as members may be harmed by erroneous or malicious information, so too may be corporations. Corporate security weaknesses may be described and disseminated through cracker communities; network attacks may be organized in the same way. Companies may fear liability if advice promulgated in an online community leads to

product failure or product-related damages. Customer complaints can be shared very rapidly with large numbers of people and can snowball into widespread mobilization. The Intel Corporation had to manage a wave of Internet protest, much of it organized through Usenet groups, as it learned about and took steps to correct a flaw in its Pentium processor in 1994. Ultimately, of course, fixing the error benefited Intel and its customers (Uzumeri and Snyder 1996). In a different case, members of a number of Internet groups mobilized to protest the introduction of a new household database product created by the Lotus Development Corporation, a protest that led to the withdrawal of the planned product (Culnan 1991). Online communities are not the only means of mobilizing discontent on the Net (e.g., Gurak 1997), but when they are characterized by member commitment, they can be particularly potent. In some countries, corporate desire to protect reputation or other assets or government desire for citizen control may collide with individuals' rights to freedom of expression (see Kranich 2004).

Intellectual-property infringement is another area of potential harm for corporations. Trademark infringement is widespread in many consumer communities. Copyright infringement can be particularly troublesome for media property companies. Fan community members create and discuss fan fiction—that is, new story lines or alternative plot endings for their favorite shows, movies, or characters. Corporations routinely issue cease-and-desist orders against these groups, fearing loss of copyright control (Jenkins 2002; Silberman 1996). As with mobilizing discontent, online communities are not the only mechanism on the Net for intellectual-property infringement. Unauthorized media file sharing represents a larger area of intellectual-property harm for media companies at the moment, but the social reinforcement that is generated when community members praise or critique one another's (arguably, intellectual-property infringing) creative work can be potent.

RESEARCH METHODS AND ISSUES

Much of the research on online communities is supported by two broad research traditions, which can be informally labeled as "insider studies" and "outsider studies." Participant observation studies began with Howard Rheingold's (2000) description of *The Well*, a Northern California online community begun in 1983. Examples of scholarly ethnographies include those of a soap opera discussion community (Baym 1999), a social MUD (Kendall 2002), a lesbian café (Correll 1995), an IRC arts community (Danet 2001), and an online game community (Steinkuehler 2006). In each case the writer/analyst was a member of the community for an extended period. The ethnography evokes the language, personalities, beliefs, interpretations, and daily lives of people inhabiting these worlds from the perspective of a member/researcher (Wilson and Peterson 2002).

"Outsider studies" typically extract records of online behavior or attitudes for study outside the community context. Linguists may extract text records for linguistic analysis of online talk (e.g., Herring 1996, 2001). Sociologists may analyze text records to understand norm development and strength or identity development (Forman,

Ghose, and Wiesenfeld 2006; Sassenberg 2002; Moon 2004). Social psychologists may use questionnaires to survey community members about their social support systems in the online world and the offline world (e.g., Cummings et al. 2002; Mackenna and Bargh 1998). Sociologists and political scientists may use questionnaires to survey members about their social and civic activities and attitudes (Kavanaugh 1999; Wellman and Haythornthwaite 2002).

Online communities are appealing subjects for researchers. New or newly visible social phenomena are intrinsically interesting to the social scientist. Moreover, online access to one's subject of study offers beguiling efficiencies. Ethnographers can do ethnographic work without leaving the office. Survey researchers can administer questionnaires to multinational samples of respondents without buying a single postage stamp. Linguists have access to entire cultural corpora in digital form. The efficiencies are not problem-free, however. Ethnographers have a missing or incomplete picture of their community members' offline lives. Survey researchers often have no access to passive community members—ones who never post (e.g., Nonnecke and Preece 2000). Linguists do not see private or back-channel communication. Still, despite the drawbacks, the past 10 years have seen a substantial growth in social science research oriented toward understanding online communities.

Whether researchers use insider or outsider data-collection methods, they must confront issues of base rates and generalizability. Researchers typically study active communities and active members within those communities. It is easy to overlook the fact that many, if not most, online communities exist in name only, analogous to ghost towns in the physical world. For example, most open source projects hosted on SourceForge have no users; fewer than half of all Usenet groups are active; more than 60 percent of blogs have not been updated in more than 2 months (e.g., Henning 2003). Even within active communities, many members are free riders, and requests for interaction may not be reciprocated. For example, even though Wikipedia has more than 200,000 registered contributors, fewer than 3500 of them do 70 percent of the work. In some Usenet groups, 25 percent of questions go unanswered. In their designs and reports, researchers should acknowledge the likely base rates of the phenomena they are interested in and take care not to imply greater frequency or impact than the base rates warrant.

Whereas general principles of ethical research are widely shared within the academic social science community (and are governed by federal regulation), procedures for implementing those principles in research on online communities are under debate. Consider just the principles of informed consent and participant anonymity. If a person's words in an online community discussion are considered private, consent should be obtained before analyzing them. If they are considered public, consent should be obtained before quoting them (except for fair use). If a researcher plans a participant observation study, she or he should seek permission from community members before beginning the study. Because most communities are open, members who join after the study has begun do not have

the same opportunity to give or revoke permission, however. When publishing results, the researcher must honor promises of anonymity by disguising participant identity. Yet powerful full-text search engines can use verbatim text, even with no identifier, to find the original (identified) source. Bruckman (2002) pointed out that norms in the humanities, in contrast with those in the social sciences, encourage attribution and reproduction. Several scholarly and professional associations are currently grappling with the ethics of online research (Frankel and Siang 1999; Kraut et al. 2003; Thomas 1996).

CONCLUSION

The Internet has been a home for self-organizing voluntary groups since its inception. As the Net grew, so did the pace of people and technology, mutually adapting to form and support new online communities of interest (e.g., Boczkowski 1999). Despite the large number of online communities and online community members today, the social form has been widespread for less than a decade. The nature of the Net means that experimentation and evolution into new variants of the social form can occur rapidly. The next 10 years should see more new community types, new ways of aggregating microcontributions, and new community processes.

The social form is also immature in terms of impact on members and on the offline world, but with a more differentiated view of community types, we should be able to better specify which types of online communities should or could have which kinds of impacts on which types of members. Nevertheless, people also live in the offline world. The biggest online community design payoffs may come from supporting online extensions of the places where people live, work, send their kids to school, recreate, vote, and worship (e.g., Hampton 2001). Television has had an enormous impact on family communication patterns, teen culture, political activity, and consumer behavior. Most of the decisions that led to those impacts were made by relatively small numbers of wealthy and influential individuals. In online communities, by contrast, everyone has the opportunity to shape the processes that will make a difference.

GLOSSARY

Dot-Com: Internet sites or businesses designed to make money during the late 1990s.

Internet Relay Chat (IRC): A program for simultaneous text communication among two or more users.

Listserv: A program for managing a distribution list of e-mail addresses.

MUD Object-Oriented (MOO): Text-based virtual reality environment in which users can program objects that have persistence.

Multi-User Dungeon/Domain/Dimension (MUD): A text-based virtual reality environment, initially used for fantasy games, now also used for social and professional purposes.

Seti@home: An activity organized over the Net in which people donate idle CPU cycles to process data looking for radio signals.

Usenet: A system of electronic bulletin boards.

Virtual Reality (VR): A text-based or graphics-based environment that evokes a self-contained world.

Wiki: A specific type of editable Web-based document collection.

INTRODUCTION

Mobile commerce is the buying and selling of goods and services or the exchange of information in the support of commercial activities through wireless handheld devices such as cellular telephones and personal digital assistants (PDAs). Mobile commerce enables users to access the Internet and conduct transactions with monetary value from anywhere, anytime. The success of mobile commerce relies on building on the established habits and practices of the consumers, and on the infrastructure, and then having additional benefits due to mobility. For instance, the added benefits may include instantaneous access and delivery, flexibility, convenience, personalization, location awareness, and better customer service. In addition, ease of use, convenience, and ensuring security and privacy should be salient features of mobile commerce.

The increase in the demand for applications dealing with moving objects can be seen in recent years. Furthermore, mobile phones and/or wireless PDAs have evolved into wireless terminals that are global positioning system (GPS)-enabled. In addition to wireless computing devices, tracking of other moving objects such as boats, trucks, automobiles, airplanes, and soldiers is also of growing interest. With the great demand on mobile devices, mobile commerce has become a gigantic market opportunity. The market for mobile business users is expected to increase from today's 77 million to over 109 million users by 2009. As many as 25 million wireless phone subscribers in North America could be using their mobile phones as mobile wallets by 2011, reports In-Stat (www.in-stat.com), a high-tech market research firm. The mobile customer base of the GSM (global system for mobile communications) family of technologies has grown to 1.85 billion users to make up more than 81 percent of the wireless mobile market worldwide, with total subscribers of code division multiple access (CDMA) at less than 300 million and a 13 percent market share (3G Americas 2006).

Worldwide, mobile commerce revenues are expected to exceed \$88 billion by 2009 (Juniper Research Group 2004).

According to the same Juniper Research Group report, it is expected that retailers will make up to \$40 billion in sales from customers who will use mobile phones to spend cash on everything from cinema tickets to hourly car parking. According to a study by International Data Corporation (IDC) (www.idc.com), mobile entertainment will be worth \$8 billion in Western Europe in 2008. The purchases consumers make will consist mainly of low-priced items, or what the industry calls "micropayments." It is also expected that RFID and infrared technologies will likely have a major influence on the future development of devices that allow for payments. The market for location-aware mobile applications such as mobile shopping, mobile advertising, mobile retailing, mobile entertainment, and mobile online banking is very promising. Figure 1 provides an overview of the essential mobile commerce components. We will review each of them in this chapter, with the exception of the standards and policies.

Figure 1: Mobile commerce: The big picture

MOBILE COMMERCE APPLICATIONS

As content delivery over wireless devices becomes faster, more secure, and scalable, it is believed that the mobile commerce market may exceed the traditional e-commerce. Mobile commerce applications can be categorized into the following classes: business-to-business (B2B),

business-to-consumer (B2C), consumer-to-consumer (C2C), business-to-employee (B2E) (Lehmann and Lehner 2004), and government-to-citizen (G2C). Although security is not important in some information-service applications, it is of significant importance in certain transaction-oriented applications. For example, a cellular phone can be used as a personal trusted device (PTD). In such cases, mobile customers may use it to purchase goods and services that may typically include gas, soft drinks, and tickets to a football game, or to check their bank balances. In such scenarios, the mobile service calls for confidentiality, integrity, and identification and authentication requirements.

Many aspects of the mobile communications industry, including the importance of mobile communications and mobile applications, and the competitive landscape of the mobile phone market have been explored based on competing protocols or standards, airtime carriers, and handset providers (Kumar 2004). Table 1 summarizes different types of applications (not an exhaustive list) and their categories. We describe these applications in detail.

Mobile Financial Services: These services encompass: (1) mobile banking, through which customers access their bank accounts and pay their bills using handheld devices, and (2) mobile brokerage, through which customers obtain stock quotes that are displayed on their handheld devices and conduct trading using these devices. In both cases, the mobile customer uses his or her PTD to set up a secure session to the bank on his PTD.

Mobile Telecommunications Services: These include services provided by telecommunication companies, in which customers use their handheld devices for the purposes of service changes, bill payment, and account reviews.

Mobile Information Provisioning: These services include the delivery of financial and sports news and traffic updates to mobile customers. Other information-service provisioning applications include integrated information services, such as tourist services, traffic coordination, management, way-finding, weather reports and forecasts, stock quotes, traffic jams, travel itineraries and nearby restaurants, news updates, sports news, business and technology news, local town information, telephone directory, restaurant guide, dictionary service, and cooking recipes, among others.

Mobile Security Services: Many public-safety and security-related services can be provided through mobile devices, as one can track and pinpoint the location of the

device. These safety-related services include: (1) tracking and locating stolen cars as well as automatically notifying the owner, (2) remotely controlling the car, for example, disabling the car engine, honking the horn, or starting the engine using a mobile device, (3) tracking of groups of vehicles and sending an alert when a vehicle crosses a predefined area, (4) alerting when a laptop moves beyond certain predefined areas, (5) tracking children, people with Alzheimer's disease or other mental disabilities, and pets, and automatic notification to the mobile users, (6) sending remote-control commands via phone or Web to let someone into the house, turn down the thermostat, or start an appliance, (7) enabling transmission of messages to individuals in emergency situations using a reverse 911 service, and (8) helping in dispatching 911, delivering real-time information on crime mapping, and providing access to federal and state databases and mug shots.

Mobile Remote Shopping: The mobile phone user browses in a wireless application protocol (WAP)-enabled shop, selects the desired goods, and pays for them with funds from his or her bank account or credit-card company. These include services or retail purchases as consumers are given the ability to place and pay for orders on-the-fly.

Mobile On-Site shopping: A mobile user may select the desired goods in a retail store and use his or her PTD to pay by logging on to the store's Bluetooth wireless LAN.

Mobile Ticketing: The user browses a WAP ticketer's site, selecting and paying for a ticket for a movie, a show, or a game. All ticket information is stored in the PTD's transaction database. At the venue, the user goes up to one of the wireless access nodes on the premises (similar to an ATM), calls up the ticket information from the PTD's database, and sends it via Bluetooth to this access node, which then prints out the user's ticket.

Mobile Advertising: This includes personalized, location-aware and context-sensitive advertising, as mobile devices are ideal for marketing channels for impulse buying (using short messaging service [SMS]-based or multimedia messaging service [MMS]-based technologies). For example, mobile users can be pushed information related to nearby hotels when they are not in their home location, nearby movies during evenings and weekends, nearby restaurants based on their preferences, etc.

Mobile Entertainment: This may include location-based games, character download, horoscope and fortune telling, karaoke information, hit songs, download ring tones, club event information, etc.

Table 1: Categories of mobile commerce applications

Category	Application
B2B	Advertising, location-based services (e.g., supply chain management)
B2C	Financial services, telecommunications services, information provisioning, security services, remote shopping, on-site shopping, ticketing, advertising, entertainment, location-based services
C2C	User-to-user applications, wireless videoconferencing,
B2E	Wireless videoconferencing, reporting, claim processing
G2C	Security services

Wireless Videoconferencing: Voice over IP (VoIP) and full-motion video communication over both WiFi and universal mobile telecommunications system (UMTS)-based networks to create videoconferences that can be billed.

Mobile User-to-User Applications: Share applications such as mobile games, pictures, cartoons, or personal files with friends and colleagues via a handset, user-to-user content provision, conversational applications (which provide means for bidirectional communication with real-time end-to-end information transfer) such as videoconferencing, groupware (collaborative work), messaging applications (which offer user-to-user or user-to-user group communication) such as messaging of photographs and video.

Location-Based Services: It has been estimated that worldwide revenues from location-based services would reach \$9.9 billion by 2010 (Steinfeld 2004). The demand for location-based services (LBSs) can be categorized into the following types (Rao and Minakakis 2003):

1. *Location and navigation service:* Maps, driving directions, directory and yellow-page listings, and business descriptions in a given geographical radius all constitute this service. These types of LBSs have become popular in Japan, while they are a more recent phenomenon in the United States. GPS capabilities may allow customers to find their way to their destinations and alert friends and colleagues to their whereabouts. If a person is relocated, they may use mobile LBSs to familiarize themselves with their new surroundings. Examples also include getting detailed maps and directions, real-time alerts on traffic conditions, and information about highway services such as gas, food, and lodgings. Although auto manufacturers are investing in making mobile platforms for cars, currently relatively inexpensive handheld devices are serving this purpose. These include devices such as golfing assistants mounted on golf carts that provide everything from course maps to teeing tips, fish finders that combine sonar and GPS capabilities to allow anglers to pinpoint the locations of schools of fish, and people locators, which enable parents to locate children in urban areas and shopping environments (Spagat 2002).
2. *Point-of-need information delivery:* This service is to request usable, personalized information delivered at the point of need, which includes information about new or interesting products and services, promotions, and targeting of customers based on more-advanced knowledge of customer profiles and preferences, automatic updates of travel reservations, etc. For example, a wireless shopping site can be designed to target users with content such as clothing items on sale, based on prior knowledge of their preferences and/or knowledge of their current location, such as proximity to a shopping mall (Venkatesh, Ramesh, and Massey 2003). To deliver such LBSs, service providers require access to customers' preference profiles either through a proprietary database or through an arrangement with an LBS provider, who matches customer profiles to vendor offerings. In order to implement such services, customization and personalization based on

the location information, customer needs, and vendor offerings is required.

3. *Industrial and corporate applications:* This type of LBSs find their way into a number of applications, including tracking material through the supply chain and inventory, tracking physicians, patients, and equipment in the hospitals, etc. This relies on the deployment of RFID technologies, which is becoming inexpensive and will likely be used by a number of retail businesses, such as Wal-Mart.

BUSINESS MODELS IN THE M-COMMERCE ENVIRONMENT

A number of business models are being practiced by the vendors of mobile commerce. Notable ones among these include: (1) user-fee business model, (2) shopping business model, (3) marketing business model, (4) improved-efficiency business model, (5) advertising business model, and (6) revenue-sharing business model (Sadeh 2002). These are described briefly below.

User-Fee Business Model

Under this model, payment can be based on a subscription fee, or based on usage. This model is best suited for regularly updated content such as customized news and location-sensitive weather and traffic conditions. In reality, the content provider may rely on the mobile service provider to implement it and collect the appropriate fee. The obvious advantages of adopting a subscription-fee-based model over the user-fee model are that it is easier to collect the fees, and the income is relatively better predictable. However, the user-fee model would be more attractive to one-time or infrequent users.

Shopping Business Model

Under this model, the traditional Internet companies sell their goods and services through the new mobile medium to offer better services and convenience to reach their customers, and moreover to capture additional customers. Essentially, the traditional Internet companies seek a mobile presence. Payment is done with the mobile device, but typically involves a third party, such as a credit-card company or a bank.

Marketing Business Model

The traditional brick-and-mortar companies push the information about their products and services through the mobile channels directly to the mobile customers. However, the customers make their payments using traditional payment mechanisms without using their mobile devices.

Improved-Efficiency Business Model

Companies adopt mobile Internet to reduce their operating costs. Such services include mobile banking, mobile ticketing, etc. Whereas the shopping business models are those adopted by traditional Internet companies to expand their

customer base, the improved efficiency business models offer mobile services to reduce their operating costs.

Advertising Business Model

This may typically involve gathering the profiles and preferences of mobile customers and targeting the advertising based on the location, time, and preferences. Typically, the advertiser passes on the information to the content provider, who would deliver the advertisements that are relevant to the user's queries. The advertiser pays for the content provider either as a flat fee, based on the traffic (number of ad impressions) or based on the performance (number of click-throughs or call-throughs).

Revenue-Sharing Business Model

Under this model, the mobile content owner uses the services of a mobile content provider. This is suitable in cases in which the content provided by a single owner is not sufficient to attract the attention of the mobile customer or is not valuable as standalone information. In such cases, the content provider combines the content from different owners and may enhance it with value-added information before delivering it to the mobile customer. For example, local weather reports, local traffic conditions, stock quotes and news updates can all be combined appropriately by the content provider. Typically, the content provider collects the payment and shares it with the content owners.

ENABLING TECHNOLOGIES

Mobile commerce has emerged as a result of the developments in several technologies. In this section, we review the advances in these different technologies that have propelled the growth of mobile commerce.

Mobile Devices

Mobile devices such as smart phones and personal digital assistants have reached new levels of usability, performance, and computing power. Increasingly, these devices are equipped with wireless-communications capabilities and location technologies. In order to exploit the m-commerce market potential, a number of industry initiatives have taken place to enable secure and reliable mobile commerce transactions. Handset manufacturers such as Nokia, Ericsson, Motorola, and Qualcomm are working with carriers such as AT&T Wireless and Sprint to develop WAP-enabled smart phones, transforming a mobile phone into a PTD. In addition, IBM and other companies are developing speech-recognition software to ensure security in mobile commerce transactions. Using Bluetooth technology, smart phones offer fax, e-mail, and phone capabilities all in one, paving the way for m-commerce to be accepted by an increasingly mobile workforce. The new generations of wireless networks such as UTM provide much better speeds and always-on connectivity.

Wireless Networks

The enabling technologies for m-commerce include wide area wireless communication technologies, short-range

wireless communication technologies such as WiFi and Bluetooth, and RFID technologies. In the following, we review their evolution over different generations—1G through 4G, of wide area wireless networking technologies, as well as short-range wireless technologies. Based on the technology use, the market growth in global GSM users has increased to 1.25 billion, global CDMA users to 202 million, global TDMA users to 120 million, and total 3G users to 130 million (www.cellular.co.za/stats/stats-main.htm). According to Pyramid Research (2004), WiFi users will surpass wireless wide area network users, and it is expected that by the year 2008 the number of WiFi users will reach 180 million, whereas that of 3G would be less than 100 million.

1G

The first generation of wireless technologies used analog transmission, which operates in the 800-MHz band and uses 30-KHz channels using frequency division multiple access (FDMA). It was introduced in North America in 1985 as advanced mobile phone service. Because of the limited bandwidth, this soon exhausts the available channels, thereby limiting the number of subscribers. Since digital signals can be compressed, enabling more effective use of the frequency spectrum, it was natural to use digital technology.

2G

The second-generation systems, which digitize not only the control link but also the voice signal, appeared in the early 1990s; they use time-division multiple access (TDMA) and CDMA. Unlike 1G, which primarily supports voice signals, 2G networks are capable of supporting voice, data, paging, and fax services. Moreover, they provide better quality and higher capacity at lower cost to consumers. GSM (global system for mobile communication) was the first commercially operated digital cellular system based on TDMA.

2.5G

One of the major enhancements of 2.5G over 2G is using the packet-switching technology. The general packet radio service (GPRS) is based on packet-switching technology, which sends packets of data over a radio wave (on the GSM network). It is a 2.5G mobile communications technology that enables mobile wireless service providers to offer their mobile subscribers packet-based data services. GPRS was standardized by the European Telecommunications Standards Institute (ETSI), but today is standardized by the Third Generation Partnership Program (3GPP).

With GPRS, a maximum speed of up to 171.2 kbps can be achieved, which is almost ten times faster than the current circuit-switched data services on GSM networks. But realistically they currently only have a maximum downstream speed of 50 kbps and upstream 10 to 28 kbps. Speeds will also depend on which GPRS version an operator uses, as well as how busy the network is at a particular time. In addition to achieving higher transmission speeds, unlike the users served by circuit-switching networks, GPRS users are "always connected."

GPRS data transmission technology is optimized for “bursty” communication services such as wireless Internet/intranet and multimedia services. It is also known as GSM-IP (Internet protocol) because it will connect users directly to Internet service providers. As a result, with GPRS, all Internet/intranet applications, such as Web browsing, chat, e-mail, telnet and FTP, multimedia services, and instant messaging, can be totally supported over the mobile network. GPRS therefore offers a smooth add-on to integrate into existing networks and supplements today’s circuit-switched data and short message service. Future applications may have the ability to remotely access and control in-house appliances and machines. Voice calls can be made simultaneously over GSM-IP while a data connection is operating—depending on the phone class and type. Although users are always connected and always online, they may still be charged only for the amount of data that is transported.

3G

The 3G mobile phone technology enables the transmission of high-quality video images in the 2-GHz frequency band and realizes new mobile multimedia communications services. NTT DoCoMo was one of the first in the world to begin research and development on W-CDMA, a key foundation for 3G mobile phone technology. The universal mobile telecommunications system (UMTS) is a 3G mobile communications technology that provides wideband CDMA radio technology. With data rates up to 2 Mbps, UMTS provides increased capacity, increased data capability, and a far greater range of services. A variation of CDMA, called time division synchronous CDMA (TD-SCDMA) was proposed by the China Wireless Telecommunication Standards (CWTS) group, which uses the time division duplex (TDD) mode. The CDMA technology offers higher-throughput, real-time services, and end-to-end quality of service (QoS), and is capable of delivering pictures, graphics, customized infotainment, streaming video, video messaging to locational services, and other multimedia information as well as voice and data to mobile wireless subscribers. UMTS is standardized by the 3GPP. Another technology, EDGE/EGPRS, is implemented as a bolt-on enhancement to 2G and 2.5G GSM and GPRS networks, making it easier for existing GSM carriers to upgrade to it. EDGE/EGPRS is a superset to GPRS and can function on any network with GPRS deployed on it, provided the carrier implements the necessary upgrades. EDGE can carry data speeds up to 236.8 kbps in packet mode and will therefore meet the requirement of the International Telecommunications Union (ITU) for a 3G network, and has been accepted by the ITU as part of the IMT-2000 family of 3G standards. EDGE is generally classified as 2.75G network technology. Another technology, the evolution-data optimized (EvDO), can reach higher rates, up to 4.9 Mbps.

4G

The 4G mobile services are the advanced version of the 3G mobile communication services. The 4G mobile communication services provide broadband, large-capacity, high-speed data transmission, providing users with high-quality interactive multimedia services,

including teleconferencing, color video images, 3D graphic animation games, and audio services. In addition, 4G networks are expected to offer global mobility, service portability, and scalability at lower cost. They are based on orthogonal frequency division multiplexing (OFDM), which is capable of having hundreds of parallel channels. The data-transmission rates are planned to be up to 20 Mbps. This technology allows seamless merging between different wireless standards, allowing one mobile device to move from indoor networks such as wireless LANs and Bluetooth, to cellular, to radio and TV broadcasting or to satellite communications. NewLogic claims that 4G digital IP-based high-speed cellular systems will account for 14 percent of total mobile wireless data revenues in 2007 and 50 million subscribers by the end of 2007; the 4G infrastructure sales could reach up to \$5.3 billion during 2007 (NewLogic 2003).

Wireless LANs

Wireless LANs are also widely used for mobile commerce. IEEE 802.11 or WiFi (short for wireless fidelity) is a family of networking protocols, developed by the working group 11 of IEEE 802. WiFi is a trade term promulgated by the Wireless Ethernet Compatibility Alliance (WECA) and is used in place of 802.11b. Products certified as WiFi by WECA are interoperable with each other even if they are from different manufacturers. A user with a WiFi product can use any brand of access point with any other brand of client hardware that is built to the WiFi standard. WLANs are cheaper than wireless wide area network to install, maintain, and use, and are relatively mature technologies.

The 802.11 family currently includes three separate protocols, 802.11a, 802.11b, and 802.11g; 802.11b was the first widely accepted wireless networking standard, which was later followed by 802.11a and 802.11g (<http://grouper.ieee.org/groups/802/11>).

802.11b

802.11b has a range of about 50 m and a maximum throughput of 11 Mbps; 802.11 runs in the 2.4-GHz spectrum and uses carrier sense multiple access with collision avoidance (CSMA/CA) as its media access method. Extensions have been made to the 802.11b protocol to increase speeds to 22, 33, and 44 Mbps, but the extensions are proprietary and have not been endorsed by the IEEE.

802.11a

The 802.11a standard uses the 5-GHz band, and operates at a raw speed of 54 Mbps. It has not seen wide adoption because of the high adoption rate of 802.11b, and because of concerns about range: at 5 GHz, 802.11a cannot reach as far as 802.11b.

802.11g

In June 2003, a third standard for encoding was ratified—802.11g. This works in the 2.4-GHz band (like 802.11b), but operates at 54 Mbps raw, or about 24.7 Mbps net, throughput like 802.11a. It is fully backward-compatible with 11-Mbps 802.11b. It uses OFDM (orthogonal frequency division multiplexing) technology, and enables

streaming media, video downloads, and a greater concentration of users without interference.

802.11n

In January 2004 IEEE announced that it would develop a new standard for local area wireless networks. The real speed would be 100 Mbps, and so up to 4 to 5 times faster than 802.11g, and perhaps 50 times faster than 802.11b; 802.11n offers a better operating distance than the above networks.

802.11i

This is an amendment to the 802.11 standard specifying security mechanisms for wireless networks. The draft standard was ratified on June 24, 2004, and supersedes the previous security specification, wired equivalent privacy (WEP), which was shown to have severe security weaknesses. WiFi protected access (WPA) had previously been introduced by the WiFi Alliance. It implemented a subset of 802.11i and makes use of the advanced encryption standard (AES) block cipher; WEP and WPA use only the RC4 stream cipher. In addition to improved encryption, it includes improvements in key management, user authentication through 802.1x, and data integrity of headers and contents using counter-mode/CBC-mac protocol (CCMP).

Bluetooth

Other wireless technologies include the short-range technologies such as Bluetooth, which can play an important role in applications such as mobile payments. It is an industrial specification for wireless personal area networks (PANs). Bluetooth provides a way to connect and exchange information between devices like personal digital assistants (PDAs), mobile phones, laptops, PCs, printers, and digital cameras via a secure, low-cost, globally available short-range radio frequency. Bluetooth lets these devices talk to each other when they come in range, as long as they are within 10 m of each other. Every device can be configured to constantly announce its presence to nearby devices in order to establish a connection. The protocol operates at 2.45 GHz and can reach speeds of 723.1 kbps. In order to avoid interfering with other protocols that use the 2.45-GHz band, the Bluetooth protocol divides the band into seventy-nine channels and changes channels up to 1600 times per second.

Bluetooth should not be compared to WiFi, which is a faster protocol requiring more expensive hardware that covers greater distances and uses the same frequency range. While Bluetooth is a cable replacement creating personal area networking between different devices, WiFi is a cable replacement for local area network access, which has a data rate of 2.1 Mbps.

One of the ways in which Bluetooth technology may become useful is in VoIP. Bluetooth may be used for communication between a cordless phone and a computer listening for VoIP and with an infrared peripheral component interconnect card acting as a base for the cordless phone. Cars can also install hands-free Bluetooth technology that allows users with Bluetooth-equipped cell phones to make use of some of the phone's features.

Radio-Frequency Identification

Another emerging wireless technology is radio-frequency identification (RFID). RFID is a method of remotely storing and retrieving data using devices called RFID tags. An RFID tag can either be attached to or incorporated into a product. RFID tags can be either active or passive. Passive RFID tags do not have their own power supply, but can respond to incoming radio-frequency signals. The range of passive tags can vary from 10 mm to 5 m. These tags cost less than \$0.25. The aim to produce tags for less than \$0.05 may make widespread RFID tagging commercially viable. Active RFID tags have a power source, have longer ranges, and contain larger memory than their passive counterparts. Active tags may have ranges in the order of tens of meters, and a battery life of up to several years.

There are four different kinds of tags commonly in use, their differences based on the level of their radio frequency: low-frequency tags (between 125 and 134 KHz), high-frequency tags (13.56 MHz), ultra-high-frequency (UHF) tags (868 to 956 MHz), and microwave tags (2.45 GHz). Low-frequency tags are primarily used for identification of subjects such as children and for animal identification and tracking, for antitheft systems, etc. High-frequency RFID tags can be used to track library books, pallets, airline baggage, and retail goods as well as for building access control. UHF tags can be typically used in pallet and container tracking, and truck and trailer tracking in shipping yards. Microwave tags can be used in long-range access control of vehicles. Some tollbooths use RFID tags for electronic toll collection (e.g., the EZ-Pass system).

Using RFID tags may have a number of advantages over bar-code technology. Unlike bar codes, which are the same for the same type of product, RFID codes are unique for each product. As a result, a product may be individually tracked as it moves from location to location, from manufacturers to wholesalers to retailers and finally to consumers. This may help companies to combat theft and other forms of product loss and can be used for point-of-sale automatic checkout, with the option of removing the tag at checkout. Moreover, cards embedded with RFID chips are widely used as electronic cash, for example, to pay fares in mass-transit systems and/or retails. EPCglobal is working on an international standard for the use of RFID and the electronic product code (EPC) to be used in tracking goods along the supply chain. It includes members from EAN International, Uniform Code Council, The Gillette Company, Procter & Gamble, Wal-Mart, Hewlett-Packard, Johnson & Johnson, and Auto-ID Labs. Futuristic uses include monitoring the expiration dates of the food in the refrigerator, etc. In summary, RFID technology can be used for collecting information from moving objects, and can also be used in applications such as supply chain management, advanced product tracking, inventory control, warehouse management, checking compliance regulations, recall, enhancement, accountability, and documentation.

However, RFID technology may raise a number of privacy concerns, as the tags affixed to products remain functional even after the products have been purchased and taken home, and can be read from a distance without

the knowledge of the purchaser. This information can be potentially used for surveillance and other purposes that are not related to the supply chain inventory functions. Another privacy concern is due to RFID's support for anticollision, in which a reader enumerates all the tags responding to it without them interfering with each other. As a result, all but the last bit of each tag's serial number can be deduced by passively eavesdropping on the RFID reader. Juels, Rivest, and Szydlo (2003) have proposed a selective blocking approach using a blocker tag, as a way of protecting consumers from unwanted scanning of RFID tags attached to items they may be carrying or wearing. A blocker tag is a cheap passive RFID device that can simulate many ordinary RFID tags simultaneously and thus blocks RFID readers from reading the actual RFID tag. It can do so universally by simulating all possible RFID tags. Or a blocker tag can block selectively by simulating only selected subsets of ID codes, such as those by a particular manufacturer, or those in a designated privacy zone. Juels and Brainard (2004) extended the blocker tag approach to enforce flexible privacy policies in which partial or scrubbed data are revealed about private tags, in lieu of the all-or-nothing policy enforced by a blocker tag. Privacy-related guidelines proposed by EPCglobal include the requirement to give consumers clear notice of the presence of EPC and to inform them of the choice that they have to discard, disable, or remove EPC tags (www.epcglobalinc.org/public_policy/public_policy_guidelines.html).

Table 2 (partially from Umar [2004]) summarizes the bandwidth and range of different wireless technologies.

Other Technologies

Location Technologies

Although location technologies have been around for a number of years, they have evolved rapidly in recent years because of the increasing use of mobile applications. They can be broadly classified into outdoor and indoor technologies. Outdoor technologies include global positioning system (GPS), network-assisted GPS (A-GPS), time of arrival (TOA), uplink time of arrival (UL-TOA), enhanced observed time difference (E-OTD), and cell of origin (COO) (Andersson 2001). Indoor technologies include Active Badge system, developed by Olivetti Research Ltd.

(ORL), PARC by Xerox, Shopping Assistant by AT&T Bell Laboratories, and Cyberguide by the Georgia Institute of Technology, among others. Although most mobile applications rely on outdoor technologies, indoor technologies have limited applications, such as the computerized visitor guides in museums. Wireless networks can provide approximate information about the location of a customer; this information exists as part of the routing information in the wireless network. GPS provides more accurate location but requires some add-in to the mobile device. This technology is typically used for driver assistance systems and in military applications such as guided missiles. For indoor applications, other technologies are used, such as the smart badge that was developed by Xerox Labs in the United Kingdom.

Application Protocols

The emerging technology behind m-commerce is the set of protocols called the WAP, which provide functionality similar to the traditional Internet protocols such as the TCP/IP, secure socket layer (SSL), hypertext transfer protocol (HTTP), and other application protocols. It is typical that the translation between the two sets of protocols is performed by some middleware at the mobile support station (MSS), which is part of the infrastructure of the wireless provider. (More details on WAP are provided in the next section.) The middleware services that connect the back-end services to the mobile devices provide translation between the different communications and applications protocols at both sides. WAP also includes a markup language based on extensible markup language (XML), called the wireless markup language (WML). IMode-enabled Web sites use cHTML, a subset of the familiar HTML 4.0 (Barnes 2003) that has been developed with the restrictions of the wireless infrastructure in mind, such as the limited bandwidth and high latencies of the networks, and small screens and limited functionality of the devices. Essentially, it removes certain features of conventional HTML, such as tables and frames. Mobile services equipped with WAP have been widely accepted, and the mobile devices equipped with Web-ready micro-browsers are much more common in Europe than in the United States. This growth is partly driven by the GPRS, WAP, Bluetooth technologies, and their use in mobile commerce applications.

Table 2: Bandwidth and range of different wireless technologies

	Data Rate	Range
Bluetooth	1 Mbps	10+ m
IEEE 802.11a	Up to 54 Mbps	<50 m
IEEE 802.11b	11 Mbps	100 m
IEEE 802.11g	Up to 54 Mbps	100 m
3G Cellular	Up to 2 Mbps	Cell sizes 5 to 10 km
RFID	Up to 2.45 Gbps	Up to tens of meters
Satellites	64 kbps	Thousands of miles

Semantic Web Technologies

M-commerce is benefiting from emerging technologies such as Web services, .NET technologies, and Ontologies. Several new technologies and standards are affecting the design of m-commerce applications. These include semantic Web technologies such as RDF, DAML, DAML-S, DAML+OIL, and OWL and service interaction technologies such as the universal description, discovery, and integration (UDDI) specifications. The .NET framework is the programming model for developing, deploying, and running Web services and applications. Web services are units of code that allow programs written in different programming languages and on different platforms to communicate and share data through standard Internet protocols such as XML, simple object access protocol (SOAP), Web Services Description Language (WSDL), and UDDI. They allow easy building of Web-based applications, including enterprise resource planning (ERP), customer relationship management (CRM), e-commerce, messaging and calendaring functionality, work-flow services, and the like.

Languages

Another driving force to mobile commerce is the standardization of programming language for mobile devices. Languages such as Java 2 Mobile Edition (J2ME) makes it possible to write powerful applications that can leverage and integrate the different capabilities of the device, including voice, telephony, security, communications, and location capabilities. These standards are geared for devices with small memory, and therefore are suitable for mobile devices.

ARCHITECTURAL COMPONENTS

A mobile communication network protocol should deliver similar functionalities provided by the different layers of the open system interconnection (OSI) model for enabling communication in the mobile Internet. Because destination nodes are mobile, traditional IP protocols are no longer applicable for the mobile communication environment. In the wired network, the convention is that the IP addresses are organized such that nodes in the same location have the same prefixes. This no longer holds, as the nodes themselves are moving and do not have a fixed location. To overcome this problem, it uses the concept of care-of-address, and employs tunneling. Essentially, under the mobile IP, each mobile node sends its location by sending its care-of-address to its home agent. The home agent then tunnels the packets destined for the mobile node by forwarding them to the care-of-address; they are then delivered to the mobile node. Several standards are in place today; however, they differ in the way in which they have adapted the standard transport and the network layer protocols of the TCP/IP. For example, the mobile IP is now part of the 3G standard; however, other standards such as the GPRS support only a simplified version of the mobile IP.

While the IP layers are responsible for routing and addressing, the TCP layers are responsible for the reliable delivery of the packets, assembling the packets in the right order, and finally handing them over to the

target application. The TCP protocol is also responsible for congestion control to ensure graceful performance degradation. With respect to the mobile communication version of the TCP protocol, it has to address specific problems because connections are often lost and transmission errors are more common in the mobile communication environment; therefore, round-trip times are harder to predict.

In addition to adapting the TCP/IP to the mobile communication environment, the mobile Internet needs to take into consideration the limited power, memory, computing capacity, and screen size of mobile devices. Moreover, because of the unreliable network connections, even the most common protocols, such as the HTTP, do not work well. Furthermore, the Web languages responsible for displaying the Web content, such as HTML, are required to be modified.

WAP has been proposed as a standard to address these challenges. The WAP forum (www.wapforum.org) was originally founded in the summer of 1997 by Ericsson, Nokia, Motorola, and Unwired Planet for the purposes of defining an industry-wide specification for developing applications over wireless communications networks. Forum members represent over 90 percent of the global handset market, as well as leading infrastructure providers, software developers, and other organizations. The WAP Forum has now become part of the Open Mobile Alliance (OMA). The WAP forum with Open Mobile Architecture formed the OMA, which has several working groups; one of them is on mobile commerce. A comparison of the Internet and WAP technologies has been provided in Figure 2. WAP architecture, as published by the WAP Forum, is shown in Figure 3. More details of the WAP are discussed below.

WAP

WAP is the de facto standard for information services on wireless terminals. It is an intelligent messaging service for handheld mobile devices such as mobile phones. WAP is an application communication protocol, and is used

Figure 2: A Comparison of WAP and Internet technologies (Source: WAP Forum) (CDPD = cellular digital packet data; IDEN = integrated digital enhanced network; PDCP = packet data convergence protocol; UDP/IP = user datagram protocol/Internet protocol; USSD = unstructured supplementary service data; WDP = wireless datagram protocol)

Figure 3: Architecture of the WAP gateway (Source: WAP Forum) (CGI = common gateway interface)

to access services and information. It is an application environment and a set of communication protocols for wireless devices designed to enable mobile users to have technology-independent access to the Internet and advanced telephony services. In particular, WAP specifications define a set of protocols in application, session, and transport layers of the communication protocol, as well as provide transactional and security services.

WAE

WAP also defines a wireless application environment (WAE) comprising of a micro-browser, scripting facilities, e-mail, Web-to-mobile-handset messaging, and mobile-to-telefax access. It allows digital content to be displayed on special WAP-enabled GSM mobile phones in a standard text format. It uses the wireless markup language WML (not HTML) to create Web applications for mobile devices so that they can be displayed in a WAP browser. As such, WAP is a protocol designed for micro-browsers. The WAP standard is based on Internet standards (HTML, XML, and TCP/IP). WML is defined as an XML application. It consists of a WML language specification, a WML script specification, and a wireless telephony application interface (WTAI) specification.

The functions of the different layers of the WAP are as follows: The WAP datagram protocol (WDP) is the transport layer that sends and receives messages via any available bearer network, including SMS, USSD, CSD, CDPD, IS-136 packet data, and GPRS. The wireless transport layer security (WTLS), an optional security layer, has encryption facilities that provide the secure transport service required by many applications, such as e-commerce. The WAP transaction protocol (WTP) layer provides transaction support, adding reliability to the datagram service provided by WDP. The WAP session protocol (WSP) layer provides a lightweight session layer to allow efficient exchange of data between applications. The HTTP interface serves to retrieve WAP content from the Internet requested by the mobile device. WML is based on XML. It is used to create pages that can be displayed in a WAP browser. The WML Script is a restricted JavaScript language used by WML to run simple code on client machines. WML pages do not embed WML scripts, but only contain references to script URLs. Similar to the Java script, the WML scripts also need to be compiled into byte code on a server before they can run in a WAP browser. WAP uses a micro-browser to accommodate the small screens of the wireless devices. The micro-browser is a lightweight piece of software to display information written in WML and to interpret WML script.

SECURITY AND PRIVACY ISSUES

Similar to the traditional electronic commerce in the wired world, mobile commerce is also vulnerable to a range of security threats. However, since mobile commerce is a radio-frequency-operated system, it is easier to perpetrate some types of attacks compared to those in wired systems. The security requirements include: (1) confidentiality: requires the messages be kept secret from unauthorized recipients, (2) integrity: requires that messages are unaltered during the transit from the sender to the receiver, (3) authentication: requires ensuring that each party is who it claims to be, (4) nonrepudiation: guarantees that neither the sender nor the recipient can deny that the message exchange took place, and (5) replay attack prevention: ensures that any unauthorized re-sending of messages is detected and rejected. Several standards have been established in WAP to provide security at the application, transport, and management levels, which are described below.

WTLS

The basis of WAP security is in the wireless transport layer security (WTLS) protocol, which is analogous to the Internet's transport layer security (TLS) accomplished using the standard SSL protocol. WTLS is similar to the TLS, with a few differences. However, WAP 2.0 uses TLS instead of WTLS to overcome the WAP gap vulnerability (discussed next), and to provide end-to-end security at the transport level. It provides security services, including authentication and digital signatures, confidentiality by encrypting data, integrity by using hashing for detecting data modifications, and denial-of-service protection by TLS that detects and rejects data that have been replayed or not successfully verified. The WML script enables a user to digitally sign a message using the public key infrastructure (PKI).

Elliptic curve cryptography (ECC) is emerging as an attractive public key cryptosystem for mobile and wireless environments. Compared to traditional cryptosystems like RSA, ECC offers equivalent security with smaller key sizes, which results in faster computations, lower power consumption, and memory and bandwidth savings. As such, this is a more suitable choice for mobile devices, since mobile devices typically have limited CPU space power, and network connectivity. In fact, traditional signature schemes are viewed as impractical to implement in the wireless environment, as they require much more processing, memory, and storage resources, as compared with those with ECC. The keys for elliptic

curve are typically on the order of six times smaller than equivalent keys in other signature schemes—for example, 164 bits versus 1024 bits. This creates great efficiencies in key storage, certificate size, memory usage, and digital-signature processing. ECC is fully supported by the WAP security standards and has been widely accepted by WAP device manufacturers.

The WAP identity module (WIM) is a tamper-resistant computer chip that resides in the WAP-enabled device—that is, mobile phones and PTDs. It is used to store the user's private key, the root public key of the PKI, etc. Mostly, WIMs are implemented using smart cards that typically have a CPU, some memory, and storage for data and programs. WML Script Crypto API (WMLSCrypt) is an application programming interface that allows access to basic security functions in the WML Script Crypto Library (WMLSCLib), such as key-pair generation, and encrypt and decrypt data, generate and verify digital signatures, store keys and other personal data, and control access to stored keys and data. WMLSCrypt also allows WAP applications to access and use the security objects and basic security services managed by other WAP security standards. WML script may optionally use a WIM Module to provide the crypto functionality. Wireless profiled TCP (WP-TCP) provides connection-oriented services. It is optimized for wireless environments and is fully interoperable with standard TCP implementations on the Internet.

Wireless Application PKI (WPKI)

WPKI is not an entirely new set of standards for PKI, but it is an optimized extension of traditional PKI for the wireless environment. It is concerned primarily with the policies that are used to manage mobile business and security environment by WTLS/TLS and WMLSCrypt in the wireless application environment. The WAP Forum provides the standards for WPKI. It requires the same components used in traditional PKI. However, the mobile device's applications and registration are implemented differently, and a new component referred to as the PKI portal is also required. The mobile device application in WPKI is implemented such that it runs in the WAP device. It relies on the WMLSCrypt application programming interface (API) for key services and cryptographic operations as well as including the traditional PKI functionalities. WPKI is an optimization of the traditional Internet Engineering Task Force (IETF) PKIX standards for the wireless environment. More specifically, it comprises optimized PKI protocols and certificate format as well as cryptographic algorithms and keys. As opposed to using the traditional basic encoding rules (BER) and distinguished encoding rules (DER) to handle PKI service requests, WPKI protocols are implemented using WML and WMLSCrypt. Similarly, the WPKI certificate format specification is a new certificate format for server side certificates, which significantly reduces the size as compared with the standard X.509 certificate. Another significant reduction in the WPKI certificate can be attributed to ECC, with the savings in the size typically more than 100 bytes because of the smaller keys needed for ECC. WPKI has also limited the size of some of the data fields of the IETF PKIX certificate format. Since the WPKI certificate format is a subset of the PKIX certificate format, it is

possible to maintain interoperability between standard PKIs.

The WAP Gap

One of the major security breaches in mobile commerce is due to the mobile network infrastructure used. When user information is transmitted from one mobile network to another, all the encrypted data need to be decrypted in order to send it to another network. When mobile devices make requests to Web pages of a network server, these requests originating from the WTLS protocol need to be translated at the originating WAP gateway. They are then encrypted, typically using SSL, and sent to the destination network. This is then processed by the HTTP in the destination network. During the translation process from one protocol to another, the data are required to be decrypted and then reencrypted. Because the data are in cleartext, they are vulnerable to attacks if an intruder can gain access to the mobile network. This vulnerability is commonly known as the WAP Gap. To alleviate this problem of WAP Gap, Juul (2002) proposes three alternative solutions: putting the WAP gateway inside the server, application layer, and mobile Internet.

Location Privacy

Identifying the location of a mobile customer is required because: (1) To function effectively, location-based services require information about the location of the communication device. As described in the section on "Mobile Commerce Applications," the location-based services present a major new market for the mobile industry. (2) In countries such as the United States, the European Union, and Japan, laws require that mobile telephones be able to provide location data with a fairly detailed accuracy for the purposes of emergency situations.

Unlike the Internet, location information has the potential to allow an adversary to physically locate a person, and therefore most wireless subscribers have legitimate concerns about their personal safety if such information should fall into the wrong hands. The 1996 Telecommunications Act included location information as customer proprietary network information (CPNI), along with time, date, and duration of a call and the number dialed. Because of the sensitive nature of location information, legal and regulatory approaches for controlling access to location information should be different from other CNPI. Specifically, consumers must be comfortable that they have control over who can obtain location information and when such information can be obtained in order for them to be willing to buy location-based services. Laws and rules of varying clarity, offering different degrees of protection, have been or are in the process of being enacted in the United States, the European Union, and Japan (Ackerman, Kempf, and Miki 2003).

Beresford and Stajano (2003, 2004) have proposed techniques that let users benefit from location-based applications, while preserving their location privacy. Mobile users, in general, do not permit the information to be shared among different location-based services. Primarily, the approach relies on hiding the true identity of a customer from the applications receiving the user's

location, by frequently changing pseudonyms so that users avoid being identified by the locations they visit.

GLOSSARY

802.11b: (also referred to as **802.11 High Rate** or **WiFi**) Applies to wireless LANs and provides 11-Mbps transmission (with a fallback to 5.5-, 2-, and 1-Mbps depending on range and signal strength) in the 2.4-GHz band. 802.11b uses only DSSS (direct-sequence spread spectrum; DSSS is one of two types of spread spectrum radio). 802.11b was a 1999 IEEE ratification to the original 802.11 standard, allowing wireless functionality comparable to Ethernet.

3G: Third-generation wireless. Refers to developments in mobile communications. Increased bandwidth, from 128 Kbps while moving at high speeds to 2 Mbps for fixed stations, enables multimedia applications and advanced roaming features.

AP: Access point.

CCMP: Counter-mode/CBC-mac protocol. An IEEE 802.11i encryption algorithm. In the 802.11i standard, unlike WPA, key management and message integrity is handled by a single component CCMP built around AES.

CDMA: Code division multiple access. A digital method for simultaneously transmitting signals over a shared portion of the spectrum by encoding each distinct signal with a code chip. Terminals receive the aggregated signal from the tower, and use specific codes to unbundle the signals. CDMA devices are noted for their excellent connection quality and long battery life.

DSSS: Direct-sequence spread spectrum. DSSS is a transmission technology used in WLAN (wireless LAN) transmissions, in which a data signal at the sending station is combined with a higher-data-rate bit sequence, or chipping code, that divides the user data according to a spreading ratio. The chipping code is a redundant bit pattern for each bit that is transmitted, which increases the signal's resistance to interference. If one or more bits in the pattern are damaged during transmission, the original data can be recovered because of the redundancy of the transmission.

GPS: Global positioning system. Satellite-based radio positioning system capable of providing specific location information to suitably equipped users anywhere.

GPRS: General packet radio service. An enhancement to the GSM mobile communications system that supports data packets. GPRS enables continuous flows of IP data packets over the system for applications such as Web browsing and file transfer. GPRS differs from GSM's short messaging service (GSM-SMS), which is limited to messages of 160 bytes in length.

GSM: Global system for mobile communications. A digital cellular phone technology based on TDMA that is the predominant system in Europe, but is also used widely around the world. Developed in the 1980s, GSM was first deployed in seven European countries in 1992. Operating in the 900-MHz and 1.8-GHz bands in Europe and the 1.9-GHz PCS band in the United States, GSM defines the entire cellular system, not just the air interface.

UMTS: Universal mobile telecommunications system. The ITU standard for 3G wireless phone systems. UMTS, which is part of IMT-2000, provides service in the 2-GHz band and offers global roaming and personalized features. Designed as an evolutionary system for GSM network operators, which will marry the benefits of CDMA with the interoperability benefits of GSM, multimedia data rates up to 2 Mbps are expected. There are three branches of the UMTS standard: TD-SCDMA, UMTS TDD, and W-CDMA. CDMA2000 is not UMTS.

WAP: Wireless access protocol. A set of standards that allows Web access on mobile devices. WAP is supported by most wireless networks and operating systems. It supports HTML and XML but is designed for WML.

WiFi: Wireless fidelity. This is another name for IEEE 802.11b. It is a trade term promulgated by the Wireless Ethernet Compatibility Alliance (WECA). "WiFi" is used in place of 802.11b in the same way that "Ethernet" is used in place of IEEE 802.3. Products certified as WiFi by WECA are interoperable with each other even if they are from different manufacturers. A user with a WiFi product can use any brand of access point with any other brand of client hardware that is built to the WiFi standard.

WLA: Wireless LAN. A type of LAN that uses high-frequency radio waves rather than wires to communicate between nodes.

WML: Wireless markup language. A language developed to control the presentation of Web pages on mobile phones and PDAs in the same way that HTML does for PCs. Part of the wireless access protocol (WAP), WML is an open standard and is supported by most mobile phones.

XHTML: A reworking of HTML 4.0 designed to work as an application of XML. It allows anyone to create sets of markup tags for new purposes.

INTRODUCTION

Online news is flourishing, and its use is growing (Li 2006, Introduction; Greer and Mensing 2006). We are at the beginning of the online news era. About 100 million increasingly diverse persons in the United States read news online. Internationally, the growth of online newspapers is similar. They are not only available in most nations and geographic locations throughout the world, their reach is also global (Chyi and Sylvie 2001). Research has shown that although online newspapers throughout the world are available to almost anyone with a computer and network access, they retain their local nature (Chyi and Sylvie 2001). Whereas the circulation of daily newspapers across the United States remains flat or in decline, Web sites that provide news content seem to be strong. The number of daily newspapers in the United States that are online grew about 13 percent from 2003 to 2004. Today, the number of newspapers online is almost equal to the number of newspapers that are being published (Journalism.org 2005). Newspaper Web sites, for example, grow at a yearly rate of about 11 percent in terms of visitors to their sites, with a total of nearly 40 million. One in four Internet users reads news online (Sharma 2005).

Online newspapers and online journalism in general have become a vital part of information available on the World Wide Web and the Internet. Growing numbers of people worldwide are reading news online. Since the mid-1990s, online magazines, wire services, newspapers, television stations, broadcast-cable networks, and subscription newsletters have matured to take advantage of their unique orientation and audiences. New technologies are introduced almost yearly that allow consumers new ways to obtain Web-based information. Wireless Internet technology that allows even greater access to online news and information is also growing rapidly. Airports, college campuses, business centers, downtown areas, and even entire communities are becoming wireless centers for laptop and notebook computer users and for personal digital assistant (PDA) handheld device users.

Cellular telephone users have even greater wireless access for online news and information. It is common today for individuals to read Web-based news with browsers on their cell phones. New technologies that are in development—such as flat-screen portable tablets or improved handheld devices that also serve as telephones—are likely to become popular in the future as well.

Even with new wireless technologies for a variety of receiving devices, wired online services continue to grow in their availability and in use worldwide. News consumers are embracing these new communication tools. The new communication technologies have been viewed by news organizations as opportunities to extend their reach and contact with news consumers at international levels. The result is new forms and formats of news and information, such as news headlines and breaking story alerts delivery by e-mail and messaging services to subscribers that are at the cutting edge of communication today.

This chapter focuses on the changing nature and status of online news and journalism, including that practiced by newspapers, news magazines, and television news organizations. It provides an overview of the evolution of online news, including the developing use of Web logs and wikis. The chapter outlines the most significant economic models that have failed, have succeeded, or are currently being tested. Competition among online news media is also discussed. This chapter examines the impact of multimedia and convergence on their content and staffing. It also provides brief descriptions of leading American online news organizations. The primary service models for online news and a summary of online news market sizes and models conclude the discussion.

ORIGINS OF ONLINE NEWS

The news industry worldwide is diversifying. Today's news companies throughout the world own local and national newspapers; local television stations; cable television and radio networks; AM, FM, and satellite radio

stations; general and specialized market magazines; subscription newsletter; professional sports teams; outdoor advertising companies; newsprint plants; Internet service providers; and a growing number of high-profile World Wide Web sites. These popular Web sites cover a lot of informational ground. They include news and information content, but also focus on activities such as entertainment and nightlife, business, tourism and travel, sports, and reference/research. News companies, particularly those that began as newspaper businesses several generations ago, have emerged as new enterprises in the multimedia world through expansion and contraction, redefinition, and restructuring. News companies have embraced this form of convergence and have moved fully into the digital age. They seek a unique role and function for their online news products (van der Wurff 2005).

The number of online news sites grew rapidly throughout the mid-1990s, paralleling the growth in popularity of the World Wide Web. But the origins of online news can be traced to the early 1980s. In 1983, the Knight-Ridder newspaper group and AT&T launched a revolutionary experiment to bring people news on demand through their computers or television sets. Development work on the videotext service, called "Viewtron," began in 1978, but took more than 5 years to debut. It remains noteworthy because it was a forerunner of today's online news media. Knight-Ridder Newspapers, which was bought by McClatchy Newspapers in early 2006, suspended the Viewtron operations on April 1, 1986, having fewer than 20,000 subscribers and having lost a staggering \$50 million. A similar venture at the *Los Angeles Times*, called "Gateway," also closed operations in 1986, having only 3000 users. The failed ventures left journalists wondering whether there would ever be a market for news on demand via computers (Burgess 1993; Keefe 1996). Viewtron and its partners even adopted rapidly developing, but still new, desktop PCs to their service by aggressively marketing software for PCs in 1985–1986, but it was not enough. With the right timing, Viewtron or Gateway might have become an America Online or CompuServe, distinguishing itself with a strong component of news and information. Had the service existed only 5 years later, it would have been at the cutting edge of the then-new Web.

A handful of daily newspapers were available online through proprietary online services in the 1980s. These included eleven newspapers that did an experiment with CompuServe in 1982. A few other newspapers produced online sites in 1990, including *The Albuquerque Tribune*, the *Atlanta Journal and Constitution*, and the *Rocky Mountain News* in Denver. University of Florida Interactive Media Lab Director David Carlson has outlined this development with an online media timeline on the Web (<http://iml.jou.ufl.edu/carlson/timeline.shtml>).

The *Chicago Tribune* (www.chicagotribune.com) was the first newspaper to provide same-day editorial content to America Online in May 1992. Soon afterward, the *San Jose Mercury News* (www.bayarea.com/mld/mercurynews), also a pioneer in online news, was the first newspaper to put its entire contents online on AOL in 1993. At the time, when only 3 million Americans were online, the *Mercury News*' decision to put the newspaper's Mercury Center online was simply an experiment.

Therefore, most observers regard the *San Jose Mercury News* to be the first online newspaper. It was not surprising that a San Jose newspaper would lead the way in online journalism. Given its location, it considers itself the newspaper of record for the famed Silicon Valley.

By the mid-1990s, as the Web expanded rapidly, broadcast news outlets were developing a significant presence on the Web. Broadcast and cable networks were among the earliest to put their news content on the Web, but local affiliates began to build Web sites with limited news content. The sites mostly served a promotional purpose by offering program listings, biographies and other information about air personalities, appearance schedules, and various forms of community service features.

Competitive amateur and professional sports have become a major drawing card for online news sites. Local and national news organizations have built a user base by providing information about local teams and major sports events while competition is underway. Local newspapers and television stations often offer running summaries and updated scores of events not always on television or radio. They enhance printed and broadcast coverage by offering statistics, schedules, archival content, and other information that, because of space or time limitations, cannot be published or broadcast. National news media often provide a similar service for professional teams and major college events.

There was also a growth of Web-based electronic magazines at about the same time. These topical online publications, often called "zines" or "e-zines," did not originate in printed form, but certainly were built upon the printed magazine tradition. They are often highly specialized and have been described as "independent publications characterized by idiosyncratic themes, low circulation, irregular frequency, ephemeral duration, and noncommercial orientation" (Rauch 2004, 153). Almost overnight, these energetic periodicals appeared all over the Web and received a large amount of popular media coverage and attention as the trend of the moment. The Web created opportunities for this new genre of specialized online news and information in the mid- and late 1990s and they have continued into the new century with a steady niche audience appeal. *Slate* (www.slate.com) and *Salon* (www.salon.com) are typical of successful zines. There are numerous zines on the Web today, and they attract an audience in the millions (Rauch 2004; Williams 2003).

CONVERGENCE AND THE CHANGING ONLINE NEWS WORLD

Convergence of mass media has arrived, and it is impacting online news. It is a slowly evolving process, but there is evidence of convergence in North America, Europe, Asia, and in other cutting-edge newsrooms around the world. Convergence has "amplified" the strategic importance of the Internet, wrote researchers Ju-Yong Ha, Steven J. Dick, and Seung Kwan Ryu (2003, 155). There is growing interest, they noted, in the merged content of television and other news and mass media, and it is expected to become more sophisticated in the years ahead.

An example of convergence at the regional level is the merger of newsrooms by Media General in Tampa, Florida. *The Tampa Tribune* (<http://tampatrib.com>), the morning daily newspaper serving Tampa Bay, and WFLA-TV (www.wfla.com) Channel 8, the NBC broadcast television affiliate, and Tampa Bay Online (www.tbo.com), the Web site serving both the newspaper and the television station, moved into a single facility in 2000 to share and work together in an early effort at convergence of newsrooms and technologies. The three news organizations share news resources, equipment, and staff. In fact, the large newsrooms, studios, work stations, and other facilities that are spread over several floors of the news center are anchored by a circular central news desk in the building's atrium. Journalists from each of the three news organizations staff the news desk and coordinate use of images, audio, video, wire content, local photographs, and news stories as well as other available content (Dupagne and Garrison, 2006; Singer 2004).

Convergence—the cooperation and sharing of resources of formerly separate news organizations as well as the delivery of news content through multiple means—is often viewed as an opportunity for the news media, and not as a process. Some view it as a threat to the news media because it is perceived to mean loss of newsroom jobs, more work for remaining journalists, more required skills, or a decline in the number of voices in a community. Yet others see it as the future of the news media and a chance for news to combine the best of its various media formats for consumers. They also feel that online news sites offer speed and depth to print or broadcast coverage (Kolodzy 2003; see also, Singer 2003, 2004; Deuze 2004; Dupagne and Garrison 2006).

The number of online users with high-speed connections is growing rapidly in the United States. A study by the Pew Internet & American Life Project released in 2006 said that Internet penetration increased from 58 percent of all adult Americans to 70 percent between 2002 and 2006. During the same period, home broadband penetration increased from 10 to 37 percent of adult Americans. A total of 74 million people access the Internet via broadband (Horrigan 2006). It is clear that American online users are entering the broadband age. The implications are clear. As more high-speed users are connected, more and more online news content can be accessed. This creates challenges for content providers to offer text, but also much more, such as audio, video, interactivity, and multimedia.

The best online newspapers have readily moved away from shovelware—the period when what they offered was little more than the reproduced published content of the traditional newspaper and the wire services—toward convergence. They seem to have matured past the point of scooping themselves when coverage of either the online or print edition carries a story that the other does not (Bressers and Bergen 2002; An Evolving Medium 1999; Fee 2002). Online newspapers have become stand-alone products (Greer and Mensing 2004), and online broadcast news sites have grown beyond their early promotional purposes (Chan-Olmsted and Park 2000). Not only do the best online newspapers today, such as *The New York Times*, offer much more than just the best content of the daily newspaper; they also offer an interactive Internet home for their established print edition readers

as well as nonreader residents and visitors (Apcar 2006). They offer an interconnectedness that follows a many-to-many communication mode (Li 2006, Graphic use and interconnectedness). Many online newspapers also have developed online information *portals* for their communities (Miller 2001). They want to offer readers a wide range of interactive tools and technologies to experience news and information like it has never been provided before (The Impact of the Internet 2000).

Solving the reader puzzle is a high priority among online news media editors. The issue is not only what content to offer and, for online newspapers, whether and how to make it different from print editions, but also how much control to turn over to readers. With the Web, there is more content and less editorial decision making over what is published. This has been given to a degree to readers. “With that enhanced control, it appears online readers are particularly likely to pursue their own interests, and they are less likely to follow the cues of news editors and producers,” noted media scholar David Tewksbury (2003, 694).

One of the most-publicized examples of national and international corporate media convergence was the America Online-Time Warner merger that was announced in early 2000. Some reports described it as a merger, but AOL stockholders actually owned 55 percent of the new company when the deal was completed. AOL obtained the immense resources of Time Warner, including Time Inc. and CNN, through the buyout involving \$156 billion in AOL stock. This event set the stage for dozens of multimedia and convergence opportunities for the new corporation that now includes America Online's worldwide network access, its Internet services, and its proprietary Web content, Time Warner's CNN broadcast news networks, its widely circulated and respected magazines (e.g., *Time*, *Fortune*, *Sports Illustrated*, *Money*, *People*) and news services, its cable television and broadband customers, its music library, its film library and archives, and much more. It has been characterized by one media observer as a “new age, techno-cultural behemoth” (George 2000). The AOL-Time Warner marriage, however, has turned out to be less for its owners than had been hoped. Some observers have even characterized AOL as a burden for Time Warner and, recently, the company has been looking to sell off its America Online assets (Simon 2005).

Web portals provide much more than just news content. Many traditional news media have established portals for residents and visitors of their communities and regions. The *San Jose Mercury News* (www.bayarea.com/mld/mercurynews), for example, is the daily newspaper portal serving California's Silicon Valley. It serves the Bay Area with the equally suburban *Contra Costa Times* within a site called BayArea.com (www.bayarea.com). *The Boston Globe* has established a similar portal for New England with Boston.com (www.boston.com). Online newspaper and television portals provide a gateway to a series of sites and links about a region or metropolitan area. They are also often customizable so readers can select types of information displayed on the home page.

For the past half decade, news organizations have scrambled to keep up with competitors to establish a strong presence on the Web. In some studies, Internet use

for reading and viewing news has been found to exceed traditional news media such as magazines and radio. One study found it approached the use levels of network and cable television (Internet Growing as News Medium 2002).

Online news media are working to define themselves. This has been difficult for news organizations, whether they are based in traditional news media or are independents and only on the Web. For online newspapers, the effort to determine the role and model in which to work has already gone through several iterations. There will be more to come. Just like radio and television before it, the newest technologies undergo a formation period. Online newspapers are experiencing an era of exploration and self-determination. Although there are no geographic boundaries for online newspapers, practically speaking, most people who access a local newspaper do it for local news. Online newspapers differ from most online news media in their intensely local nature, provided by the content they offer from their print editions (Singer 2001).

Online news media have matured with coverage of major breaking and ongoing stories, such as Operation Iraqi Freedom and the 2006 and 2004 election campaigns. The growth of blogging is one example. More traditional television, radio, newspaper, and magazine journalists use blogs as an extension of their reporting and as a means of presenting informed opinion expression. Furthermore, there are a wider number of innovative presentation formats for the breaking stories covered, for features, and for the opinions expressed (Palser 2003). Despite this view, some experts feel the news media have been stagnant and have not gone far enough. Experimentation and new online publications and formats continue to debut in a search for what works best for contemporary audiences (Reeves 2003). The University of Florida's new media expert David Carlson (2005) is typical of those who feel that online news media have incredible potential but do not yet live up to it. Carlson believes that "The problem with online newspapers is this: They are just like offline newspapers. That means they are not particularly interactive, they are barely customizable to individual preferences, they contain mostly outdated information, and they are hardly relevant to most readers' daily lives" (p. 68).

Formation of new media can trigger transformation of established media. New media may also have a destabilizing effect on old media, but old media also tend to embrace the new media (Samoriski 2002). For example, the development of television brought on change in movie news reels and, ultimately, their disappearance in theaters. However, it is also common for new media to complement and benefit existing outlets (Samoriski 2002). For example, print newspapers might advise readers to go online for more information not offered in the printed editions because of space limitations, or they can offer links to multimedia content—such as interviews with key newsmakers, photo galleries, video and audio of major events as they occurred—available on the newspaper's Web site.

Some authorities have offered views that another stage of online news change is in the near future. With the maturity of online advertising, with growing revenues,

online news may experience a growth of stand-alone sites in the second half of this decade. Although first attempts at these failed, for the most part, some observers feel the time is right for these sites as well as the branded online editions of print news organizations and television networks to prosper (Dorrer 2005).

Online newspapers require professional abilities and skills different from their print counterparts. While both forms require news judgment, speed, and other fundamental journalistic tools, online newspapers seek content producers with greater versatility to work in multimedia as well as computer network technologies (Dupagne and Garrison 2006). Old skills-based walls have been taken down in favor of individuals who can do it all—write, edit, compile, tell the story visually, and work with audio and video content. The changing staff needs have forced some online newspapers to recruit beyond their own newspaper newsrooms. News companies will continue to look for specialists in different skills areas such as print and television, but will also increasingly seek "multimedia superreporters," who cover the world with laptops, digital video and still cameras, and digital recorders (Gates 2002).

WEB LOGS AND WIKIS

Since the late 1990s, Web logs have developed into an influential, new online news format. Affordable and user-friendly software made it possible for anyone to maintain a Web log (Jensen 2003). A blogger can be an independent individual who is reporting from the field or who is commenting from his or her living room. It can also be someone who is affiliated with the traditional media in a newsroom, on assignment at a remote location, or who is commenting from home (Lascia 2002). Because of this unspecific definition of what a blogger may be, there is widespread debate among professionals and scholars whether bloggers should be considered journalists (Kramer 2004; Cooper 2005; Edmonds 2005; Lascia 2002; Blood 2003; Andrews 2003). Tensions between journalists and bloggers have been growing (Kramer 2004). Bloggers usually comment on the news of the day or bring attention to stories they feel were undercovered, rather than reporting their own news (Smolkin 2004). And the existence of bloggers combined with the lack of regard held for them by traditional news media managers suggests a "perilous future" for print media (Cooper 2005).

However, aside from the debate over professional standards, Web logs have had a great impact on online news. Web logs were instrumental in breaking the news about the Lewinsky/Clinton scandal in 1998, which led to the impeachment of President Bill Clinton, and the Trent Lott scandal in 2002, which led to the resignation of the U.S. Senate Majority Leader (Williams and Delli Carpini 2004). During the 2004 presidential campaign, Web logs became known to a more widespread audience. Howard Dean, who sought the Democratic Party presidential nomination, based part of his 2003–2004 campaign effort on blogs. Some bloggers discredited a CBS News report on President George W. Bush's National Guard service and others were invited by Republicans and Democrats to cover the national conventions (Perlmutter and McDaniel 2005). In the

corporate world, Web logs have also had a great impact. For example, Web log attention caused lock producer Kryptonite to lose approximately \$10 million because a posting in 2004 detailed how to open one of its bicycle lock products (Kirkpatrick, Roth, and Ryan 2005). Web logs also function as watchdogs over the traditional media. The resignations of CNN executive Eason Jordan and White House correspondent Jeff Gannon were instigated in early 2005 by the relentless reporting of bloggers (Kurtz 2005).

According to the search engine Technorati (2006), there were almost 38 million Web logs in the United States in spring 2006. But they are a truly global phenomenon. In China—the second largest Internet market in the world—Tsinghua University research estimated 37 million Web logs and about 60 million bloggers in 2006 (Reuters 2006). Some of the most prominent political Web logs are Instapundit (www.instapundit.com), DailyKos (www.dailykos.com), Power Line (<http://powerlineblog.com>), and Eschaton (<http://atrios.blogspot.com>). At the same time, the number of Web log readers worldwide is also steadily increasing. In 2005, 26 percent of Americans were very or somewhat familiar with Web logs (Cable News Network 2005). The number of Internet users who read Web logs increased from 17 percent in February 2004 to 27 percent in November 2004 (Rainie 2005). The credibility of Web logs is also increasing. Web-log users view Web logs as more credible than the traditional media (Johnson and Kaye 2004).

In recent years, another new information format developed parallel to Web logs—wikis. Although Web logs are generally written by a single person, wikis are a collective effort of a group of contributors. Individuals can add, edit, and delete content on these Web sites. The most prominent wiki is the online encyclopedia Wikipedia (www.wikipedia.org), which in the summer of 2007 had 1.9 million entries in English. The encyclopedia is also available in German, French, Japanese, Polish, Italian, Swedish, Dutch, Portuguese, and Spanish. Wikipedia has been called one of the greatest success stories of the Web (Dodson 2005), yet the Web site was at the center of a discussion about the reliability of information it offers in entries (Seigenthaler 2005). Besides Wikipedia, several other widely used wikis have developed. Wikinews (www.wikinews.org) and Wikimedia (www.wikimedia.org), for example, attempt to collaboratively gather news and conduct reporting and provide a collaborative collection of information resources, respectively (Weiss 2005).

ONLINE NEWS WRITING AND CONTENT

Online journalism has the opportunity to take the best features and characteristics of existing mass media and news media, eliminate most of the weaknesses, and place them into a new medium in which stories can be told in new ways using words, video, audio, and still photos together. To accomplish this, online news writing is evolving. It is, of course, quite different from newspaper, broadcast, or other news media writing. To be truly valuable to users, online news must take advantage of hypermedia and hypertext and their unique nonlinear nature.

Writing for online news sites is often done in layers (e.g., headlines, summaries, leads, and other text), often called “chunking,” and with an awareness of clicking and scrolling capabilities of browser software. Online storytelling should involve the wide variety of media forms available on the Web, not just basic text and images. This includes audio, video, and forms of reader-user interactivity such as chat rooms and instant opinion polls.

Another important part of writing for online newspapers is its style. Each publication develops its own style. Sometimes, it is personal, casual, and informal. Other approaches can be more formal. Often the style used is a function of the audience served (Rich 2007; Whittaker 2000; Wilber and Miller 2003). Although the Internet allows storing long articles easily, the compact style has not been abandoned. News writers still strive for brevity for many of their stories in order to display an entire story in one screen view without scrolling.

Online newspapers have a struggle similar to that of their print counterparts. Both are fighting for survival in a digital- and video-oriented world. With countless other online news sources coming from television, radio, and magazines, competition for online newspapers is intense. Add to the mix a new set of news providers—online services such as Google, Microsoft Network, America Online, and Yahoo!—and the job becomes much more difficult. If, as some AOL executives maintained, AOL is used by many of its customers for news and information instead of local online newspapers, the electronic editions of traditional newspapers and other news media have a long road ahead for success. As one critic wrote, online news consumers and journalists should “be afraid” of such ventures (Koerner 2001, 25).

The evolution of online newspapers has paralleled the development of other online news media (An Evolving Medium 1999; Strupp 1999). They are learning what works and what does not. Newspapers have offered electronic mail alert services for breaking and ongoing stories, severe weather bulletins, or even more routine notifications of new editions of their publications (Outing 2001; Langfield 2001). While interactive features, such as electronic mail used for news alert services and bulletins, have been successful, Web-based chat rooms have not been used as effectively (Perlman 1999; Pryor 2000). By the end of its first decade, online news has moved from a more passive and noninteractive model to more immediacy, content richness, and control given to users-readers (Bucy 2004).

Major U.S. natural and human-made tragedies, such as Hurricane Katrina during August 23–30, 2005, the terrorist attacks on September 11, 2001, and the student shootings at Columbine High School in Colorado on April 20, 1999, provided situations in which to use interactivity, but many online newspapers were criticized for failing to use them well (e.g., see Perlman 1999; Outing 2001). Other research has also shown less use of interactivity and hypertextuality than might be expected in online media and criticism that the medium of online newspapers remains immature (Oblak 2005; Salaverria 2005). At the very least, research has shown adoption of multimedia and interactivity in online newsrooms to be dependent on organizational structures and work practices, among other factors (Boczkowski 2004).

Newspaper sites have become quite popular during this learning period, but newspapers continue to learn how to use their Web edition to attract and serve readers and advertisers (Palser 2005; Pryor 2000). For example, the use of interactive features to enhance reader feedback seems to be growing in newspaper newsrooms (The Impact of the Internet 2000). Although there is growth in sophistication in developing news content, the same cannot be said about commercial endeavors that would support the news product. Electronic commerce and advertising opportunities remain a mystery to many in the industry. Online newspaper managers certainly have not learned everything necessary about turning the sites into profit centers for the company, but neither have other online news organizations at this point. The online news industry is so young that it has remained uncertain how its costs will be paid (McMillan 1998; Pryor 2000; Palser 2001, Pay-per-click; Chyi 2005).

SEARCHING FOR THE BEST ECONOMIC MODEL

It is a strange form of contradiction. On one hand, Internet users have been gradually convinced that they should buy music online. And services such as iTunes are earning revenues today after music lovers downloaded their favorites online for free. But pay for news online? Not yet. Although there are notable exceptions, such as *The Wall Street Journal* subscription fees and the premium content services subscriptions of *The New York Times* and CNN, most Internet news consumers love to read information online—at work, on the road, and at home—but they “loath to pay for it,” as Katharine Seelye (2005, 17) wrote. In fact, *New York Times* Company Chairman and Publisher Arthur Sulzberger, Jr., effectively expressed the position of newspapers in the online age. He stated that “If we’re going to define ourselves by our history, then we deserve to go out of business” (Gates 2002). “Newspapers cannot be defined by the second word—paper. They’ve got to be defined by the first—news. All of us have to become agnostic as to the method of distribution. We’ve got to be as powerful online, as powerful in television and broadcasting, as we are powerful in newsprint.”

Newspapers, more than any other traditional news medium, raced to go online during the mid-1990s. In 1994 and 1995, they offered content for free. But some owners and managers felt they could charge for the content and switched to online subscriptions. This was short-lived, however, as the experiment failed when users found comparable information elsewhere on the Web (Grimes 2002). Owners and managers had expected to be part of a digital gold rush (Dibean and Garrison 2001), but the anticipated gold rush never came because the medium has not found a profitable economic model. To date, there simply has not been sufficient advertising volume and other revenue to support online news. News on the Web, some have observed, spreads very quickly, has a short shelf-life, and can be found for free if a user searches hard enough (Grimes 2002; see also Arampatzis 2004).

There are numerous business models for Web content, including the failed videotext model, the failed paid

Internet model, the failed free Web model, the failed Internet/Web advertising “push” model, the present portals and personal portals models, and the evolving digital portals model (Picard 2000). Online news organizations are experimenting today with portal approaches. Within the various portal models, the subscription model may be the future despite previous failed efforts (Chyi 2005). Financial conditions often lead to such radical change, and the economic environment in late 2001 and 2002 following the September 11 terrorist attacks against the United States, combined with a recession, put pressure on sites to generate income. Online advertising was not producing sufficient revenue, and sites were forced to find a different economic model. Suddenly, the subscription model looked better and, as one publication in 2002 stated, “the free lunch is over” (Smith 2002, February; see also Smith 2002, April, and Trombly 2002). The collapse of free alternatives will lead consumers to accept the subscription or other fee-based models for operation of online news sites. Commercial sites with valued content have already found this to work. Arampatzis (2004) identified six basic subscription model variations currently in use:

1. Free content; advertising supported; paid subscription content and paid premium content.
2. Free content; advertising supported; ad-free access paid subscriptions.
3. Paid subscriptions; no or very limited free content; no advertising.
4. Paid subscriptions; no or very limited free content; advertising accepted.
5. Free content to in-market Internet users; paid subscriptions for out-of-market.
6. Regional content providers cooperate in charging scheme, everyone charges.

The Wall Street Journal and its online site, for example, had more than 768,000 worldwide subscribers in late 2005 (Christie and Edmonds 2006). “We already know that consumers will pay for highly valued, proprietary content that either makes or saves them money,” *EContent* writer Steve Smith wrote (2002, February, 19). “For most other content brands, however, it gets more complicated. The fear of competition from free alternatives, the risks of severe traffic loss, and the overwhelming resistance among users has left the fee-based approach more of a pipe dream.”

Despite this surge toward fee-based content, it is apparent that consumers have been conditioned to expect to find news online at no cost (Donatello 2002). Online users see the Web as an open frontier that is free to all, and they adamantly oppose paying even modest fees (Chyi 2005). Since 1997, some online newspapers ceased publication for lack of profitability. Some online newspapers have recently begun using registration schemes to begin orienting consumers toward paid subscriptions (Brown 2003).

Online news consumers are upscale and typically live in urban or metropolitan areas. The Pew Internet & American Life Project stated that “this information-elite . . . shapes how delivery of news and information will evolve online” (Horrigan 2006). A study of online newspaper consumers

concluded there is an undeveloped newspaper market for paid access to local information and news. The study concluded that "substantial marketing efforts" were required to develop the consumer base. Consumers, the study stated, are (a) unwilling to pay for content because they are conditioned to finding it for free, (b) they do not see "incremental value" in online news, (c) newspapers are "strong enough to lure a core audience online, but not strong enough to make them pay," (d) the process of paying for content reinforces attitudes against paying for it, and (e) consumers are willing to register and provide personal information, but not to pay cash for access (Donatello 2002, 36; see also Ekstrand 2002).

Online news media, unlike their videotext forerunners, are popular. At the very least, newspapers, radio and television stations and networks, and news magazines sustain them to maintain their brand reputations in cyberspace. But until the industry can find a successful economic model for online news to make a profit, or at least sustain its operations, it will always be a promotional service in news organizations rather than a distinct editorial voice. For several years, news organizations have been searching to find the solution for a profitable Web site. According to one national analysis, about half of the newspapers participating in a survey reported slight profits, mostly from classified advertising, but they also earned some revenue from banner advertising, sponsorships, and Web-related services fees (Trombly 2002; Noack 1999; Scasny 2001; *The Impact of the Internet* 2000).

The financial models for online news media have not had enough time to test what works and what does not. In fact, one industry expert described the development of online business models as "short and wild" (Palser 2001, Pay-per-click, 82). In mid-2007, news organizations were still searching for a way to generate even further revenue from online subscriptions and end the "free ride" given to Internet readers (Seelye 2005). Still, at least a few of these experts feel it is not a bad idea if marketed properly (Palser 2001, Retooling online news, Pay-per-click) or, if news sites offer more value, paid access will succeed (Scasny 2001). It does not appear likely, in the minds of observers, that subscription revenues will overtake and replace advertising revenues in the near future. There are too many variables, such as sector served, markets, brands involved, and prices. Online news sites must explore content and merchandise offered. Sites may have to target highly specific audiences and meet their information needs, for instance, to succeed. Ultimately, the situation seems to involve redesigning content offered to create greater demand instead of simply getting customers accustomed to paying for something they used to get for free (Smith 2002, February).

THE COMPETITIVE DIMENSION

One of the main characteristics of online news media that make them different from more traditional news media is hypertext. In the early stages of online news, Fredin (1997) noted that in order for newspapers and other media to provide a news service online, "a computer-based interactive system requires a wide range of links or choices within stories" (p. 1). While the use of hyperlinking in

online news stories has increased with the growth of the Internet (Tremayne 2004), most news organizations are only beginning to understand the uses of hypertext, linking, and integration of other media into their coverage of breaking news, features, and other information that can provide the depth and scope of coverage expected of newspapers and their online counterparts (Deuze 2003; Singer and Gonzalez-Velez 2003).

Multimedia news content distributed on the Web still has a lot of developing to do. Online audio and video quality is often a function of connection speed. Individuals connecting to an online news source with a modem or wireless device will often experience slide-show-like video and out-of-sync audio or worse (Palser 2000). Individuals with digital subscriber lines (DSL), cable modems, or faster connections still find difficulties with loading sound and video clips and getting them to play. The potential of high-speed Internet connections in enhancing online newspapers and their coverage, however, seems great no matter how it is seen today, especially for newspapers that have sister television and radio stations for shared content. When Web-based multimedia news works, it can be stunning in the same way that live television takes us to the scene of breaking stories. The recent emergence of podcasting, for instance, is a promising development in this direction (Potter 2006).

While daily newspapers almost universally have some presence on the Web, some small nondaily community newspapers do not. Research has shown that newspapers that are not online are typically not in competitive situations, nor are they owned by large media companies. If a smaller community-based newspaper goes online, it is usually because a corporate decision to do so was made elsewhere (Lowrey 2003).

Online news organizations are often restricted by their budgets and staff resources. Although these organizations may seek to use interactive and multimedia resources and to develop original content, the number of people available and their experience and skills levels, as well as the money available to pay the bills, often sets stark parameters in which the online edition operates (Arant and Anderson 2001; Fouhy 2000). In recent years, budgets of online newspapers and their staff sizes have been impacted by worsening economic conditions—increasing operational expenditures and decreasing revenues—that have led to numerous layoffs and curtailed services (Rieder 2001; Palser 2001, Retooling online news; Fouhy 2000). Survival became the focus of many online news sites as the new century began (Farhi 2000, *Surviving in cyberspace*). Some analysts have argued that such decisions were short-sighted and not in the future interests of online news (Rieder 2001; Palser 2001, Retooling online news). Cutbacks have led to greater dependence on automated Web-page production using software that builds HTML pages from news system databases, including those of the wire services.

Online managers use research about their audiences on a regular basis. It may not be conventional readership research in the same way newspapers or broadcast stations have conducted it over the years. Instead, Web-based news sites depend on traffic reports generated by software that monitors the Web site's server and visits

to and from the site and its pages. Online news sites are also using information about Web-site users, such as how long they spend reading a site's pages, to help sell advertising and to target audiences more carefully (Nicholas and Huntington 2000).

TODAY'S LEADING U.S. ONLINE NEWS SITES

It is important to note that some of the most popular online news sites are operated by broadcasting and cable companies. This underlines the popularity of television as an entertainment and news source during the past four decades in the United States. Since the 1960s, the largest proportion of Americans has used television more than newspapers, magazines, or radio for daily news and information, and that brand success has carried over to the broadcast companies' presence on the World Wide Web.

Just as they have done in the print and broadcast world, a handful of online news sites have dominated the thus far short lifespan of online journalism. This has meant a combination of sites based on the nation's leading newspapers and television networks, as shown in Table 1. These top sites have typically been identified by their visitor traffic per day or other time period, but they are also distinguished by their traditional content quality: CNN is the second-leading site overall, MSNBC is third, and Gannett Newspapers/*USA Today* and *The New York Times* offer the leading online-newspaper sites (Sharma 2005).

Table 1: Top 15 U.S. Online News Sites June 2007

	Visitors (in Millions)
All Global News	95.577
1. Yahoo! News	32.293
2. CNN Digital Network	28.321
3. MSNBC	27.434
4. AOL News	21.938
5. NYTimes.com	12.535
6. Gannett Newspapers	12.279
7. Tribune Newspapers	12.038
8. ABC News Digital Network	10.852
9. Google News	9.195
10. CBS News Digital Network	8.682
11. Hearst Newspapers Digital	8.624
12. USAToday.com	8.592
13. Fox News Digital Network	8.192
14. Washingtonpost.com	8.181
15. McClatchy Newspaper Network	7.708

Source: Nielsen/NetRatings (2007, June), Top news sites, www.cyberjournalist.net (accessed July 20, 2007).

The New York Times, MSNBC, and *USA Today* clearly are among the leaders in news brand identity (Van Wagener 2003).

The most popular online news site in the United States is the news aggregator Yahoo! News, which has no print or broadcast counterpart. Similar news sites among the most popular are AOL News and Google News. These news sites do not use editors or reporters and produce no original content. They manage information and help users to personalize their news selection (Palser 2004). Google, for instance, has an automated selection process based on its search engine's complex algorithms, by which wire stories are ranked, based on their position on 4500 other Web sites around the world (Schroeder and Kralemann 2005; Sreenivasan 2003; Loory 2005). This kind of news gathering without human intervention has been criticized as "robotic journalism" (Kurtz 2002; Loory 2005). "It does not seem likely that algorithm-driven technology can replace reporting, but it can do a lot of the work some editors now do," University of Missouri journalism professor Stuart Loory has stated (Loory 2005, 32). "Cost-conscious organizations could use it to make reductions that could greatly affect editorial decision-making."

Cable News Network (CNN)

The Atlanta-based Cable News Network, known worldwide as CNN, has become a dominant international and national news site (www.cnn.com) on the Internet. The television news network, which debuted in 1980, arrived early on the World Wide Web and established itself as one of the leading multimedia news sites in the world, just as its broadcast parent has become in the past decade. Taking advantage of its existing video and audio content and about 4000 news employees worldwide, the site combines content from the numerous television and radio services and networks with print sources to produce a news site that functions as a news portal for many users.

The site offers two editions. The U.S. edition is geared to cnn.com's largest audience. However, the site also offers an international edition (<http://edition.cnn.com>). The content on the two sites is similar in that both focus on breaking and daily news and events, weather, sports, business, politics, law, science/technology, space, health and medicine, travel, and education. The international sites are in English, but they offer readers connections to local languages. CNN offers video and a variety of interactive opportunities such as the CNN polls about current events and issues, viewer feedback, and e-mail newsletters and alerts about breaking news.

CNN's strongest attractions are its international and national coverage of news, but it also provides limited local market news through its affiliated network stations. The site has made the latest multimedia technologies, from live video streaming to audio packages, available to users. It also provides users access to searchable archives of news features and background information on the site. Like other major news sites, CNN's site is updated continuously throughout the day. *Time* and its well-established stable of international publications are available on the CNN site through a partnership with its corporate cousin.

Fox News Channel

Fox News Channel (www.foxnews.com) is a relative newcomer in television news in the United States as compared with the well-established ABC, CBS, NBC, and CNN networks, but it has come on strong in the past few years to become a popular site for online news users. The site features content related to the Fox News network news programs, the top news stories of the day, business news, sports, politics, weather, lifestyles and living, and opinion. Much of the content is generated by Fox News reporters, correspondents, and others in the Fox News Channel newsrooms around the world. The site also uses a large amount of Associated Press content.

The main sections of the site include TV Shows, which provide listings information about Fox News programs; Top Stories, which provides headlines and links to full stories about major news of the day; Politics, which focuses on international, national, and state political news from the world's capitals; Business, which offers headlines and stories on current business news and information from Standard and Poor's, financial and investment advice, and stock performance information and price quotes; and FoxLife, which concentrates on leisure activities such as movies and music, celebrities news, and other personal lifestyle news.

The Views section of the site offers opinion essays, commentaries, and columns from Fox News correspondents, news program hosts, and contributors from outside the newsroom. The Weather section provides local forecasts and conditions searches, AccuWeather dangerous weather alerts, and other almanac and historical information. The Fox News site also has a strong sports news and information presence that comes through integration with the Fox Sports Web site (www.foxsports.com). The Sports site is organized generally by sport and offers up-to-date partial and complete scores, sports programming listings, and headlines and stories of the current news cycle. Fox News provides an enhanced Web experience for its registered users.

Los Angeles Times

The *Los Angeles Times* is one of the world's leading newspapers, and a dominant news source for Southern California. Although it is internationally known, the newspaper seeks to serve its home region with its online presence. Nonetheless, in addition to its significant audience of Californians, it also has a national and international following, according to Richard Core (2002), editor of latimes.com. Core has responsibility for overseeing the editorial production of the site. Core says about half of the site's visitors come from the print edition's primary circulation area of Southern California; the other half is worldwide.

The site went on the Web in April 1995, but an earlier electronic edition, known as Times Link, was available in 1993 and 1994 on the proprietary Prodigy information system. The site has built a considerable amount of daily traffic. Core said there are about 1.7 million page views per day (the number of pages, not single advertisements, seen by users). The site offers news, sports, business, and entertainment news stories that originate from the newspaper. This is supplemented with wire service content and

video from KTLA-TV, an affiliated Los Angeles television station. But the strength of the site is the newspaper's daily and weekend coverage. "We offer the whole package that you would get from a metropolitan newspaper," Core (2002) explains. *The Times'* entire print edition is not included on its Web site, however. This includes display advertising, tables in the Business section such as CD interest rates or Sports section results and statistics, syndicated content such as comics or advice columns. Almost all of the *Times'* news stories are posted, except in extremely rare cases. Some puzzles and some photographs are also not included, but the site producers plan to improve on this.

There is free content on the site. It includes Calendar Live! Web-only entertainment coverage, guides to Southern California, specially organized special reports, a searchable restaurant guide, searchable classifieds, and audio and video content. Original content also includes multimedia such as interviews with reporters on major local stories, documents to support reporting, and wire content. The site also presents affiliated television station video and audio clips and it offers graphics such as Flash presentations. A short-lived experiment that permitted readers to rewrite editorials—labeled by some observers as "Wikitorials"—was shut down in 2005, however, because the site was flooded with distasteful content (Mills 2005).

MSNBC

MSNBC is the combined effort of Microsoft Corporation in Redmond, Washington, and NBC News in New York. The joint product of the computer software giant and one of the major news networks in the United States created both a widely watched cable television network, MSNBC, and a leading online news site (www.msnbc.com). Much of its recent popularity with online news users was due to its coverage of the Olympics, the war in Afghanistan, and terrorism threats.

MSNBC is a leader in the creation of content solely for the Web. MSNBC content producers do not offer users as much repurposed content as newspaper sites do, for example. MSNBC.com uses the resources of NBC's network television and radio operation, its business-oriented channel CNBC, and NBC affiliate stations and news services. MSNBC on the Web provides content from the collection of news programs from NBC News, MSNBC TV, and CNBC and NBC Sports broadcasts. CNBC offers extensive business content to the site, including live stock-market coverage and frequent news updates that are included on the Web site. The site prepares coverage of major daily national and international stories, updates on breaking stories, and in-depth reports on issues.

The national award-winning site is searchable and keeps stories on the site for about a week. The site also offers Webcasts featuring hourly video news updates and extensive streaming video. The site has a reputation as a leader in breaking news and original journalism on the Internet. MSNBC.com also has developed a series of partnerships that generate site content as well. These include arrangements with *The Washington Post*, *Newsweek*, *The Wall Street Journal*, ZDNet, MSN Money Central, *The*

Sporting News, Expedia, E! Online, Pencil News, *FEED* magazine, *Science* magazine, BET.com, inc.com, Space.com, Inside.com, The Motley Fool, RedHerring.com, Internet Broadcasting Systems, and Pioneer Newspapers.

In addition, MSNBC.com programs interactive content for MSNBC TV and NBC News on WebTV Plus. The breadth and depth of coverage is combined with high levels of personalization. MSNBC.com content is also available through wireless services. The site permits a large degree of user customization. These features include the ability to design a personal front page to display predetermined categories of headlines and news, current stock quotes, and sports scores. Users can also find NBC local affiliate stations' local news content on a daily basis.

The New York Times

The New York Times is one of the world's preeminent newspapers. Its online edition, called New York Times On The Web (www.nytimes.com), debuted on January 20, 1996. The site truly serves the world. Its readers come from all over the globe. Editor Bernard Gwertzman (2002), who is in charge of the entire editorial operation online, determines the home page content each day. The site draws about one-quarter of its audience from outside the United States, another quarter of its audience from the New York metropolitan area, and the rest from other parts of the United States.

The site draws high audience numbers, partly because of its print edition content but also because of original content. The content of the site varies, but reflects the general news standards of the company, Gwertzman says. All of the newspaper's National Edition is offered on the online site, although the Web site pays, Gwertzman said, "a little more attention to entertainment." During the first 2 months of the war on terror in late 2001, for example, *The Times'* site carried a photographer's journal from Afghanistan narrated by photographer Vincent Laforet. The site relies on newspaper reporters and wire services for most of the online content, but content at any given moment is a function of the time of the day.

The Times requires online users to register at no cost and it uses the demographic information it obtains to understand its market and attract advertisers. However, some content, such as its leading columnists, is available only to users of the paid premium service. Readers can subscribe to free e-mail-based news alerts for major or breaking stories. These alerts were particularly valuable to readers in the aftermath of the attacks on the World Trade Center. Major stories are a way of life at the site. The site's producers displayed the stories that won the newspaper a record seven Pulitzer Prize medallions in 2002 for its coverage of the September 11 attacks, even though it is difficult to determine whether online coverage had any impact on the Pulitzers (Kramer 2002). The site has partnerships with the *Financial Times*, *Foreign Affairs*, the BBC, and the German news magazine *Der Spiegel*.

The Washington Post

The Washington Post (<http://washingtonpost.com>) has an international and national audience. Built on the

reputation of the print brand of the national capitol's primary daily newspaper, the site has rapidly built a strong following since its debut in June 1996. Douglas Feaver (2002), executive editor, oversees content. He said the site does well providing online news and information to the Washington metropolitan area, including suburban Virginia and Maryland, as well as a large international market.

The Washington Post online has opted to present itself as a national and international online newspaper. The results have been impressive. Approximately 20 to 25 percent of the site's content is original. Feaver says about 60 to 75 percent of news content is original and about 33 percent of features are original to the site. Content is developed mostly by the newspaper's extensive staff, but it is also developed by online staff writers and Associated Press, Reuters, and Agence France-Presse wire services. Although about 240 persons are employed at washingtonpost.com, only five writers are devoted solely to developing online content. A number of other part-timers contribute news, features, business, health, and entertainment content. "We have the entire *Washington Post* and additional information that compose our content," Feaver (2002) stated. "This includes wire services, exclusive Internet stories, restaurant reviews, and audio."

USA Today

Gannett Corporation is one of the world's largest news businesses. It is the largest newspaper group in the United States, with ninety-five newspapers and a combined daily circulation of about 7.7 million. It also owns and operates twenty-two television stations. Its flagship newspaper is *USA Today*, which has a daily circulation of 2.3 million and is available in sixty countries worldwide. The company also publishes *USA Weekend*, a weekly magazine with a circulation of 24 million in almost 600 newspapers (Company Profile 2002). *USA Today* is internationally and nationally circulated five days per week and is one of the world's largest newspapers. Gannett is known for its corporate sharing, and this benefits all of its newspapers, broadcast stations, and online sites. The online edition has won national awards for its online journalism (Accolades 2002).

The Web edition is organized similarly to the newspaper, with main sections devoted to news, sports, money, and life. News includes daily coverage from the newspaper as well as columns, opinion pieces, U.S. Supreme Court decisions, health and science, and local city guides. One of the newspaper's widely recognized strengths is sports, and the online site mirrors that for Web readers. Baseball is one of the top attractions, drawing on Gannett's *Baseball Weekly*, but all other professional and amateur sports are also covered and updated regularly. The Money section offers business and financial world news as well as interactive opportunities to create and manage investment portfolios online. Small business tips are offered and consumers seeking information about automobiles find the site useful. The site's Life section reflects celebrities, television news and listings, movies and reviews, arts news, travel information, and a collection of columnists.

In addition to these sections, the site offers comprehensive and current weather information, a technology section, and a shopping section. Site visitors can take advantage of several interactive components of the site. These include "Talk Today," a chance for readers to chat online with experts and to subscribe to e-mail newsletters. Readers can subscribe to five different e-mail newsletters. These focus on the daily news briefing, daily technology report, weekly book publishing news, weekly automobile news and reviews, and weekly retail shopping deals and special offers.

The Wall Street Journal

The Wall Street Journal introduced its online edition in 1995. It has been designed to serve the business and financial communities in the United States and abroad, but it also focuses on general news, says managing editor Bill Grueskin (2002). Most of its content originates in the printed edition of the newspaper, but 2 to 3 percent, he says, is original. The original content, Grueskin described, is mostly additional feature content. From the printed *Journal*, the site uses news from its various editions. While much comes from the U.S. edition, it also depends heavily on its European, American, and Asian editions. The site's producers also place news from the Dow Jones news service and other wires on the site.

Subscriptions include access to the site's market news, research and charting, current and historical stock quotes, use of site personalization tools, e-mail and news alert services, access to the *Barron's* online edition, and access to the most recent thirty days of news archives. The online site is organized somewhat differently from the print edition. For example, Marketplace, the second section of the printed edition, does not appear as an online section. Instead, articles from that section appear online by subject. The staff of about eighty full-time reporters and editors put the next day's edition of the newspaper on the site at about midnight (ET) the evening before publication. The site provides audio and video multimedia content and interactivity such as discussions and reader feedback. The site can also be personalized for users to select priorities and preferences for content display. Its ultimate strength, in the view of editor Grueskin, is the exclusive online content.

ONLINE NEWS MARKETS AND SERVICE MODELS

News media often follow a market model on the World Wide Web that is based on geography, despite the fact that the Web and Internet have disposed of such limitations. This is often the case because the original print edition of a newspaper or television station is defined by a particular geographic orientation or signal limitation. There is much uncertainty about the economic and financial future of online news. At the least, the success or failure of online news depends on highly complex economics (Chyi and Sylvie 2001). Experts are unclear about whether online news, such as that from online newspapers, will become an economically viable business (Chan-Olmsted 2004; Chyi and Sylvie 2000). Some of this uncertainty and

confusion is market-related. What market does an online news organization serve? There are four or five common levels of service: national/international (these may also be separated), regional, local, and specialized-niche (Chyi and Sylvie 1999; Dibeau and Garrison 2001).

There are at least four models for online news functions. These include the twenty-four-hours-a-day continuous news model, the community bulletin board site model, the supplementary news site model, and the exclusive news site model. These models are neither distinct nor mutually exclusive, and two or more of them are generally found to exist within a single news site. In fact, many news sites at the national and international level in particular often use all four models at a given time. For example, if a weather threat or other natural disaster occurs, many online news sites update constantly, offer interactivity such as bulletin boards and other outlets for flow of personal information, offer supplementary coverage and information as it becomes available, and even create specialized sites devoted to coverage of that news story. This certainly happened in many communities in the United States and other nations following the terrorist attacks on September 11, 2001.

The Twenty-Four-Hours-a-Day Continuous News Model

Like the wire services and cable networks, online newspapers and broadcast television stations can be operated on an always-on-deadline or never-on-deadline circumstance (Smith 1999; Farhi 2000, *The dotcom brain drain, Surviving in cyberspace*). Some authorities argue that for an online news operation, especially traditional newspapers that have gone online, to survive in the new century, they must adopt a twenty-four-hours-a-day news radio or wire service approach. News organizations that offer constantly updated content must not only invest heavily in their Web sites, but must also provide both depth and ongoing effort to keep content current. They must be responsive to the peaks and valleys of their region (usually 10 A.M. to 5 P.M. local time) and update most intensely during the heaviest of traffic periods (Farhi 2000, *The dotcom brain drain, Surviving in cyberspace*). Some online news organizations take this approach only when major breaking news stories, such as the September 11 terrorist attacks, occur.

The Community Bulletin Board Site Model

Many online newspapers have done more than rehash their print copy. Some have opted for the community bulletin board site model. *The Boston Globe* (www.boston.com/globe), for example, was among the first major newspapers to design its online version to provide community information about events, featuring news about Boston's arts, weather, and commerce.

The Supplementary News Site Model

Some print and broadcast outlets also take advantage of the limitless space on the Web to add additional material to online news stories that appeared in their print

and broadcast versions. Many local newspapers have followed this model, serving as local equivalents of CNN, taking advantage of online timeliness by reporting local breaking news stories which, if not covered online, would be reported on local radio or television before the newspapers (Heyboer 2000).

The Exclusive News Site Model

One model that print and broadcast news organizations have not adopted is the exclusive news site model. Exclusive news sites offer news not found in other forms, such as those other news media operated by the same news corporation or company. They are more common among zines, or electronic magazines, such as *Salon* and *Slate*. To date, however, few broadcasters, newspapers, or other news outlets have posted exclusives online, and this model remains more a conceptual model than one commonly used on the Web.

CONCLUSION

Online news is flourishing, and its use is growing. This is the beginning of the online news era. In the United States and internationally; growth of online news in recent years has been significant. Online news Web sites are not only available in most nations and geographic locations throughout the world, their reach is also global. Online news is available to almost anyone with a computer and network access worldwide, yet they retain their local nature. While the circulation of daily newspapers across the United States remains flat or in decline, Web sites that provide news content seem to be strong. Online journalism in general has become a vital part of information available on the World Wide Web and the Internet. Since the mid-1990s, online magazines, wire services, newspapers, television stations, broadcast-cable networks, and subscription newsletters have matured to take advantage of their unique orientation, the interactive tools of the Web, and audiences. New technologies are introduced almost yearly that allow consumers new ways to obtain Web-based information. News consumers are embracing these new communication devices. The new communication technologies have been viewed by news organizations as opportunities to extend their reach and contact with news consumers at international levels. The results are new forms and formats of news and information, such as news headlines and breaking story alerts delivery by e-mail and messaging services to subscribers that are at the cutting edge of communication today.

GLOSSARY

Alert: Notification about a breaking news event or story by an online news service, usually by e-mail.

Banner: Form of advertising that usually contains a graphic product image or message on a Web site. The size of the ad may vary, but often spreads horizontally across the top or other part of the page. Some banner ads, however, are designed in a vertical shape.

Brand: The recognizable name of a news company that has been given to a news product on the World

Wide Web or other forms of communication on the Internet.

Convergence: Implementation of multimedia combining text, graphics, audio, and video in online news presentation as well as the combination of divergent media technologies to produce a new medium, form, or method of communicating with audiences.

Flash: Software that produces animation and video for Web pages and browsers. Content producers can quickly and easily prepare special effects through animation and other techniques, interactivity, sound, and video.

Headline: For an online news site, a brief sentence or short phrase summary of a news story, often with a brief abstract. These features are linked to longer stories and coverage elsewhere on the site.

Hypermedia: Links among any set of multimedia objects such as sound, animation, video, and virtual reality. Usually suggests higher levels of interactivity than in hypertext.

Hypertext: Organization of news and information into associations that a user can implement by clicking on the association with a mouse. The association is called a hypertext link.

Independent: An online news organization not grounded in traditional, branded news media, and only found on the World Wide Web or Internet.

Interactivity: For online news services, features such as e-mail feedback, instant opinion polls, chat rooms, and message boards that involve the site user in some form.

Market: The audience served by an online news organization. The grouping may be determined by founding or originating media markets, by geographic boundaries, specializations, or defined in other ways.

Online Journalism: News presentation on the World Wide Web or other Internet-based formats. This includes news offered by traditional news organizations (e.g., newspapers, television stations and networks, and magazines) as well as nontraditional sources such as Internet service providers (e.g., Yahoo! and America Online) and bulletin board services, Web "zines," and news groups.

Online News: Collection and presentation of current events information on the Web or other Internet-based formats, including traditional and nontraditional sources such as those discussed above under *Online Journalism*.

Package: The combination of audio, video, graphics, and hypertext components that create a news story on a Web site.

Portal: Entry points, or "doorways," to the Internet that often serve as home pages for users. These are offered by online newspapers, radio stations, and television stations and provide much more than just news content. These sites provide activity and entertainment listings, community calendars, government reference material, online interactive features, and multimedia content.

Producer: For an online news site, this is an individual who develops news content for a Web site. These individuals work with all forms of news media to prepare the coverage for a story.

Shovelware: Software that produces content of an online news site that is taken from the published content of a newspaper, television broadcast, and/or wire service.

Webcast: Live news broadcast or other video program distributed on the Web by an online news or media organization.

Web Edition: The online edition of a traditional printed newspaper. These editions often include breaking news as well as extra, and often extended, content not found in printed editions.

Web Log: (or **Blog**) Personal Web site that is prepared in dated log or diary format. It is an online journal that is regularly updated and has entries, called "posts," which are usually listed in reverse order. A blog is maintained by a blogger and the site is usually specialized and focuses on a single topic or subject area and offers information and observations from the author, contributors, or from other sites. Blogs create a community called the Blogosphere.

Wiki: A Web site that makes it possible for different users to add, edit, and delete content, with the purpose of building a collective Web site.

Zine: Independent publication on the Web that often offers idiosyncratic themes, irregular frequency of publication, ephemeral duration, and a noncommercial financial base.

INTRODUCTION

The travel industry is the world's largest industry, exceeding \$6.2 trillion in gross output (World Travel and Tourism Council [WTTC] 2005). Reports from the WTTC indicate that tourism employs over 221 million people worldwide, or approximately 8.3 percent of the global workforce. The emergence of travel as a significant economic activity began after World War II, as travel became widely accessible to the general population. As shown in Table 1, very few people traveled internationally in 1950 as measured by today's standards. Yet, from 1950 to 1970, international travel exploded, increasing by more than 550 percent. This growth in international travel

continued through the 1980s and 1990s to reach over 763 million visitor arrivals in 2004, representing over \$623 billion (U.S. dollars) in international tourism receipts. Since 1990, international travel has increased over 70 percent, and for a number of countries it has grown to be their largest commodity in international trade. Indeed, the travel industry now serves as one of the top three industries for almost every country worldwide (Goeldner and Ritchie 2002).

Information technology has played a central role in the growth and development of the tourism industry. In the early years of mass global tourism (from the 1950s to the 1970s), the technology used was largely limited to computer systems that supported the internal functions of large operators in the transportation, hotel, and food service sectors. Also, a number of central reservation systems (CRSs) and global distribution systems (GDSs)—Sabre, Amadeus, Galileo, and Worldspan—were developed first by airlines and then by hotel companies to enable travel agencies (and other similar intermediaries) to directly access schedule and pricing information and to request reservations for clients. These intermediaries became the primary users of travel information systems, thus providing important links between travelers and industry players (World Tourism Organization Business Council [WTOBC] 1999).

During the late 1980s and early 1990s these systems and the information they contained emerged as important strategic tools and highly profitable ventures, enabling system operators such as American Airlines and Hilton Hotels to grow and successfully position themselves within the overall travel market. The work of Mayros and Werner (1982) and Wiseman (1985) describes this significant development in the travel and tourism industry. An important characteristic of the growth of these systems was the inclusion of detailed behavioral information about each customer. Armed with this information, existing systems were significantly enhanced (Poon 1993).

Table 1: World Tourism Growth

Year	International Tourism Arrivals (Millions)	International Tourist Receipts ^a (Billions US\$)
1950	25	2
1960	69	7
1970	166	18
1980	286	105
1990	441	280
2000	681	496
2001	680	482
2002	700	482
2003	690	524
2004	763	623

^aInternational transport receipts excluded.
Source: World Tourism Organization (2005).

Even more important was the fact that these networks were proprietary and that the first movers in the market placed proprietary terminals with controlled content on the desks of travel suppliers and agents, thus creating high barriers to entry. As a consequence, the relationships of firms and organizations within the travel industry changed dramatically, placing emphasis on expanding strategic relationships in order to more fully exploit various business opportunities within the travel value chain.

The success of CRSs and GDSs paved the way for the Internet, enabling the travel and tourism industry to quickly exploit its many strengths. Indeed, in many ways the Internet is ideal for the travel and tourism industry. As a communication tool, it is simultaneously business- and consumer-oriented. The Internet is business-oriented because it enables businesses to communicate with potential visitors more easily and efficiently and allows them to better support and immediately respond to customer information needs through the provision of interactive travel brochures, virtual tours, and virtual travel communities. In addition, the Internet enables tourism-related enterprises to communicate with their partners more effectively in order to develop and design offers that meet the individual needs of potential visitors. The Internet is customer-oriented in that it empowers the user to easily access a wealth of information, enabling the traveler to almost “sample” the destination prior to an actual visit. Moreover, emerging ecommerce capabilities enable the traveler to make reservations, purchase tourism-related products, and share trip experiences with others.

Today, the Internet is one of the most important communication tools for travelers as well as travel and tourism enterprises. For example, studies by the Travel Industry Association of America (TIA; 2005) indicate that over one-third (37 percent) of American adults use the Internet to search for travel information and/or make reservations (see Table 2); for Americans who actually travel, this figure increases to 52 percent. Studies also show that the travel and tourism industry responded to the emergence of Internet-based technologies by adopting a number of new and innovative ways to communicate with consumers, as well as with other industry partners. As such, the travel and tourism industry is one of the most significant users of Internet technology as measured by the number of Web sites and Web pages and by online sales volume (Werthner and Klein 1999). Indeed, studies of online spending showed that in 2004 consumers spent \$53 billion online for travel, which represents about one-third of all travel spending in that year. In contrast, online retail spending amounted to just 1.9 percent of all retail spending (European Travel Commission [ETC] 2005). In addition, travel sales amount to 43 percent of all online sales, making it the most important eCommerce category (eMarketer 2005). Further, surveys of American convention and visitor bureaus show that essentially every bureau maintains a Web site, with some offering more advanced e-commerce capabilities, and surveys of the Internet indicate that over 1 billion Web pages exist supporting the travel and tourism industry (Wang and Fesenmaier 2002).

This chapter presents an overview of many of the uses of the Internet and other network technology applications

Table 2: Internet Use for Travel Planning: 1997–2005

Year	% of U.S. Adults	% of U.S. Travelers
1997	7	8
1998	18	21

by travelers and the firms and organizations that compose the travel and tourism industry. The next section provides a brief synopsis of the structure of the industry and the role of network technologies, focusing on four major sectors: hotels, airlines, travel agents (and related intermediaries), and destination-marketing organizations (DMOs). It also discusses the newly emerging travel search engines, which could fundamentally change online distribution structures. Following this introduction, emerging marketing and management strategies are considered and various issues related to the development and use of Web sites and online management information systems are discussed. The subsequent section focuses on the role of network technologies from the travelers' perspective. A variety of consumer-related technologies are considered, including travel “brochure” Web sites, virtual tours, and mobile devices. As part of the discussion, changing patterns of use and their impact on the travel experience are considered. The last section of this chapter identifies five global technology-related trends affecting the future role of network technology applications in travel and tourism.

THE TRAVEL AND TOURISM INDUSTRY

Structure of the Industry and the Role of Network Technologies

The travel and tourism industry is comprised of all organizations involved in the production and distribution of travel and tourism products. It can be viewed as an umbrella industry with a complex distribution chain (see Figure 1) containing a set of interrelated businesses, such as transportation companies, accommodation facilities, attractions, catering enterprises, tour operators, travel agents, and providers of recreation and leisure facilities, as well as a multitude of government agencies (Werthner and Klein 1999). In contrast to other industries, it is not a physical product but information that moves from suppliers to customers. To respond effectively to the dynamic character of the industry, this information must be able to flow smoothly among consumers,

Figure 1: The travel and tourism industry value chain (adapted from Werthner and Klein 1999) (CRS = central reservation system; GDS = global distribution system; LTO = local tourism organization; NGO = nongovernmental organization; NTO = national tourism organization; RTO = regional tourism organization)

intermediaries, and each of the suppliers involved in serving customer needs. As a result, information technology (IT) has become an almost universal distribution platform for the tourism industry. IT reduces the cost of each transaction by minimizing print, coordination, communication, and distribution costs. It also allows short-notice changes, supports one-to-one interaction with the customer, and enables organizations to reach a broad audience (Poon 1993). Most communications and transactions are now supported by Web-based systems; however, the Internet has not been adopted equally by all tourism sectors. Certain sectors, such as airlines, have been aggressive adopters of technology, using it to help manage and streamline their operations and to gain strategic advantages (Buhalis 2004; McGuffie 1994). Especially the low-cost carriers have long received a majority of their bookings through their Web sites, helping them keep distribution and fulfillment costs below those of other airlines. Others, such as the hotel sector, have been less enthusiastic and have only recently begun to take advantage of many of the benefits that the technology can bring (Connolly and Olsen 1999). Many traditional travel agencies are also lagging behind other sectors in terms of technological adaptation, and it is increasingly evident that experienced consumers are often better informed than professional advisers. However, given the way in which IT is reshaping the structure of both commerce and society in general, its importance to the success of all types of tourism companies can only grow in the future. As a result, tourism companies have changed dramatically the way in which they conduct their business and are under pressure to invest further in new technology in order to maintain their competitive advantage.

Hotels

The hotel industry bases much of its distribution on direct contact with customers (Nyheim, McFadden, and Connolly 2004; WTOBC 1999). Historically, hotels have

distributed information through print-based media, such as brochures, travel planners, and regional guides, and received reservations by mail, phone, and fax. Since the 1970s and 1980s, hotel rooms have been made more accessible for booking through GDSs and through direct access to hotels using CRSs. These connections were usually enabled by “switch” network providers (such as THISCO, WizCom, and Unirez) to link a hotel’s reservation systems to a GDS. Such additional network “intermediaries” added considerable cost and complexity to these legacy distribution systems. In addition, such technologies have been inadequate, as customers have traditionally not had access to these systems and travel intermediaries have experienced difficulty and delay in finding and booking appropriate hotels, whereas hotels have experienced high clerical costs in attracting and processing bookings from customers. The high level of complexity and high administration/transaction costs of these systems kept many smaller hotel properties from participating in these distribution networks. The emergence of new information and communication technologies (i.e., Internet technologies) presents new opportunities to make these processes more accessible and more efficient.

Although the hotel sector overall, as compared to other industry sectors, has been slow to use the Internet (Connolly, Olsen, and Moore 1998), many hotel managers are becoming increasingly aware of the potential distribution, promotion, and interactive marketing advantages of the Internet. The Internet offers several advantages for hotels of all sizes. One of the advantages is increased effectiveness due to cost reduction and revenue growth. Another advantage is higher-quality customer relationships due to the possibility of personal contact services and dialogue with the customer (Morrison et al. 1999; Sterne 1999). For example, customers can answer questions about their personal preferences for rooms, and based on this information, customers receive services at the hotel that are adapted to their preferences. The decision

to adopt technologies has become so important that many hospitality organizations have transformed their organizational structure to include functions and positions to oversee technology-related decisions (Nyheim et al. 2004). There are, however, many factors that may limit the use of new technology—particularly for smaller and/or independent accommodation properties, many of which have limited systems for managing inventory, pricing, and electronic distribution. Heading the list of potential barriers is the proprietary nature of customized technology solutions found throughout the hospitality industry, followed closely by closed IT architectures, lack of technology standards, limited technology skills, as well as unclear business cases or return on investment analyses associated with IT investment (Cline 2001).

Nevertheless, it is now generally agreed that Internet-related technologies are the single greatest force driving change in the hotel industry and will continue to have dramatic and sweeping implications on how hotels conduct business in the future. Hotels are expected to position themselves strongly on the Internet to take advantage of its distribution capabilities such as reach, content dissemination, feedback collection, interactivity, and one-to-one marketing. Further, current trends indicate that this greater involvement in IT by the hotel industry will increasingly encompass customer-centric approaches to capitalize on the cost structure and long-term potential of the Internet while at the same time differentiating products and building lasting value propositions.

Airlines

Air transportation systems worldwide are being dramatically affected by technological developments. Many of these developments focus on the use of Internet technology to improve the efficiency of operations (Sheldon 1997; Buhalis 2004). However, the early use of IT in the airline industry was characterized by asynchronous applications with low degrees of interactivity and integration (Jarach 2002). The first applications of computer technology to airline operations emerged in the 1950s when CRSs were designed. The primary function of computerized airline reservation systems was to simplify the process of booking flights by allowing travel agents to find relevant flight information and make reservations directly from their terminals without having to call airline reservations offices (Klein and Langenohl 1994; Buhalis 2003). Because of their many operational and cost-related advantages, CRSs became essential for the distribution of airline tickets through travel agencies.

Until the mid-1970s, airline computer reservation systems were used only for proprietary airline information, and the major airline companies all had their own CRSs (Sheldon 1997). Some of the CRSs were combined to become GDSs, which provided multiple carrier information and constituted important electronic distribution channels. The major GDSs include Galileo, Amadeus, Sabre, and Worldspan, and these are now available through the Internet. These airline reservation systems provide a number of functionalities to travel agencies, including flight schedules and availability, passenger information, fare quotes and rules, and ticketing. Most of the systems now also enable consumers to view schedules,

fares, and fare rules and to book flights. In addition to developing reservation systems as the predominant distribution channel, many airlines have invested heavily in information systems to automate other areas of airline operations and management, which can be categorized into two sections: (1) systems for streamlining operations such as baggage and cargo handling, cabin automation, and safety control, and (2) decision-support systems to aid in decision-making related to flight scheduling and planning, crew scheduling and management, gate management, and departure control.

More recently, however, airlines have increasingly focused on consumer Web sites. The main attraction for carriers in adopting a Web site is the development of a radically new distribution channel that may encourage the use of new booking and sales processes. Thus, exploitation of the Internet at the customer interface has become a key catalyst in the transformation of the airline industry (McIvor, O'Reilly, and Ponsonby 2003). Another powerful application of new technology has been developed in the area of yield-management systems. These systems integrate sophisticated databases with complex mathematical modeling, thus allowing airlines to price tickets in real time based on changing availability and booking patterns. In an industry with a product as perishable as travel, yield management has been critical to effectively manage profitability. Airlines have pioneered and still lead the development of these yield-management information systems.

Travel Agencies/Online Intermediaries

Travel agencies are intermediaries that arrange travel plans and distribute travel information to individual travelers, with some agencies specializing in certain market segments or products. In addition, many travel agencies function as tour operators, designing their own package tours and selling them either directly to the traveler or through other agents. Travel agencies use information intensely and therefore need IT to process that information. In fact, information on travel products, destinations, schedules, fares, rates, and availability is their most important product and defines their existence. The more information a travel agency can access electronically, the more timely, accurate, and efficient services it can provide to its clients.

The most prevalent application of IT in travel agencies is the GDS terminal, which was first placed in travel agents' offices by major airlines to facilitate airline bookings in the 1970s (Sheldon 1997). GDS terminals are still the major information and booking tools used by travel agents for all types of travel products. However, the advent of the Internet has significantly changed the way travel and tourism products are distributed. Increasingly, consumers can access information online, and travel agents have been forced to adapt to this change. Travel agents have an ambivalent relationship with the Internet because it can be a threat in that it makes products available directly to the consumer and yet it also provides additional business opportunities. Many travel agencies offer services on the Internet, giving them a much broader geographic consumer base than if they operated in traditional ways. They can receive bookings from clients through the Internet

and can even book passengers on flights without issuing paper tickets. Travel agents can also use the Internet as a research tool, and this might be particularly important in the future as some travel products become available only via the Internet. In addition, IT applications can be used by travel agencies to create value-added products or services through the online provision of their travel expertise in combination with the wider range of travel products and services available on the Internet. However, realizing that physical location is irrelevant in today's electronic marketplace, new types of travel agencies that exist only on the Internet, such as Expedia and Travelocity, are emerging and continue to raise the level of competition among travel agencies. Consequently, travel agencies that prosper on the Internet are those that offer specialist advice and services well beyond those available through simple booking agents.

Destination-Marketing Organizations

Destination-marketing organizations (DMOs) are typically not-for-profit, government-funded, small and medium-sized, information-intensive organizations that perform a wide range of activities to coordinate the diverse components of the tourism industry (Gartrell 1988). DMOs act as a liaison, collecting and providing information to both the consumer and the industry in order to facilitate tourism promotion and development of a specific area.

In general, DMOs have been slow to adopt IT in their operations and marketing activities (Wang and Fesenmaier 2006). It was not until the late 1980s that computer systems were adopted by the larger DMOs to enhance publications and information operations and, to a lesser extent, to support reservation services. During the late 1990s, as desktop computing technologies became more widely available, DMOs began to use IT more extensively. More and more DMO directors realized that Internet marketing was an inseparable, often critical part of their overall marketing endeavor (Yuan, Gretzel and Fesenmaier 2006). They have since developed a high level of interest in the Internet because the use of the Internet offers the potential to reach a large number of consumers at relatively low cost and provides information of greater depth and quality than traditional media. In other words, using Internet technology enables DMOs to promote their destinations' tourism products and services better, present associated organizations more equally, and collect customer information for effective customer relationship management (CRM). More importantly, the Internet allows them to improve business processes, conduct marketing research, provide customer service, and facilitate destination management and planning with less dependency on time and space. Indeed, the key to successful destination marketing efforts depends primarily on the representation and provision of timely and accurate information relevant to consumers' needs by using Internet technology (Wang and Fesenmaier 2006).

Despite this potential, DMOs have not been particularly quick in establishing a sophisticated Internet presence. Several factors have contributed to the current status of DMOs' Internet strategy. One factor is related to the complex structure and relationships of the various constituents DMOs represent. The travel and tourism

industry has a very complex structure, with a large percentage of the organizations classified as small businesses (Gartrell 1988). Among the DMOs' constituents are government agencies, marketing organizations at different levels, suppliers, and distributors. Although each entity maintains critical relationships with other entities in order to deliver the desired products and services, the enormity of this diverse industry as well as the different benefits these constituents are seeking make the job of DMOs complex and difficult.

The unique characteristics of the Internet and the capabilities required of DMOs for implementing effective Internet marketing have also been identified as important influences. Marketing is a creative and adaptive discipline that requires constant regeneration and transformation in accordance with changes in the environment (Brownlie et al. 1994; Cronin 1995). Thus, conventional marketing activities cannot be implemented on the Internet in their present form (Hoffman and Novak 1996). For Internet marketing strategies to be successful, DMOs have to be aware of the capabilities and characteristics of the Internet and need to start developing new marketing concepts and paradigms, because the Internet presents an environment for marketing activities that is fundamentally different from that of traditional media (Connolly and Sigala 2001). Despite these problems and challenges, DMOs have begun to recognize the opportunities that emerge from using the special features of the new medium, in particular the interactivity and multimedia capabilities it provides. As a result, the number of DMO Web sites is rising rapidly, offering online destination information with increasing quality and functionality. However, with the explosive growth of the Internet, destination information is available from many sources, including travelers themselves. In this extremely competitive environment DMOs have to constantly reevaluate their priorities in marketing activities to ensure their relevance. Thus, with the transparency of the Internet comes also a greater emphasis on measurement and reporting (Gretzel et al. 2005).

Travel Search Engines

Travel search engines (TSEs) constitute the latest addition to intermediaries in the tourism industry and, as in the case of CRSs, their emergence was technology-driven. Travel search engines allow consumers to conduct meta-searches of several online travel booking sites. TSEs apply sophisticated search engine technology to search a network of proprietary databases, thus giving users a wider range of options and greater price transparency. TSEs are thought of as more consumer-friendly than other online booking Web sites because they crawl the Web sites of travel suppliers more frequently, consequently generating an even broader array of choices (Eyefortravel 2005, A strategic analysis). After a selection is made from the search results, TSEs send users directly to the supplier's Web site to complete the purchase. Thus, TSEs are moving up the value chain by offering travelers a one-stop search model, enriched content, and user-friendly interfaces.

Sidestep has emerged as the leading TSE, followed by Cheapflights. Other main players include Kayak, Yahoo! Farechase, Mobissimo, and Qixo (Eyefortravel 2005, The

ultimate travel search engine). However, the TSE market is currently small and has not yet had a significant impact on the online tourism industry. As of mid-November 2004, the top six travel search engines held only a combined 0.42 percent share of all traffic to online travel sites. In contrast, Expedia, Travelocity, and Orbitz held a combined 16 percent share of online travel traffic for the same time period (EyeforTravel 2005, The ultimate travel search engine). However, TSEs have the possibility to directly impact existing revenue models in the online tourism industry because tourism suppliers consider TSEs a new marketing tool that drives traffic to their own Web sites (EyeforTravel 2005, The ultimate travel search engine). According to Hitwise (2005), the market share of visits to four of the major TSEs tripled from October 2004 to April 2005, whereas visits to the top five travel agency sites (Expedia, Travelocity, Orbitz, Yahoo! Travel, and CheapTickets) increased by only 11 percent. Hitwise also reports that visitors to top travel search engines are more likely to be older, with Mobissimo attracting the largest number of visitors over the age of 55 (25 percent of total visitors). It is expected that as Baby Boomers retire and have more leisure time, this price-conscious group will become a powerful driver of traffic to travel meta-search engines (Hitwise 2005).

Emerging Marketing and Management Strategies

The adoption of IT has transformed the way in which the tourism industry conducts business. With the assistance of new technology, especially the Internet, new opportunities have emerged for tourism organizations, which enable them to market their travel products and services and manage their daily business activities more effectively. In particular, innovative marketing and management strategies have evolved in the areas of Web development, Web advertising/promotion, e-commerce activities, customer relationship management, and the use of online destination management systems.

Web-Site Development

Hanson (2000) observed that there are three major stages in Web-site development: (I) publishing, (II) database retrieval, and (III) personalized interaction. Stage I sites provide the same information to all users. Though a stage I site can contain thousands of pages, pictures, sounds, and videos, it is limited in the dialogue it affords between the travel Web site and the user because it only broadcasts information from the Web site to the viewer. Modern Web tools make stage I travel Web sites easy and inexpensive to develop in that almost any document can be converted and moved online.

With experience and investment, the travel organization moves to stage II Web sites, which combine the publishing power of stage I with the ability to retrieve information in response to user requests. The responses are dynamically turned into Web pages or e-mail. Interactivity and dialogue have started, although this activity is limited to a series of "ask-respond" interactions. However, the ability to use Web sites as points of access to images, sounds, and databases is particularly valuable.

A stage III travel Web site dynamically creates a page catering to an individual customer. It moves beyond an "ask-respond" interaction into a dialogue and may anticipate user choices and suggest possible alternatives. A stage III travel Web site does more than just react to requests typed into forms or selected by clicking on an image. It requires the capabilities of stages I and II plus the customization of content and functions to the needs of a specific user.

DMOs use Web-based technologies in different ways and with varying intensity, owing to different backgrounds, financial resources, and marketing objectives (Yuan and Fesenmaier 2000). Some DMOs are at a preliminary stage of using Web technologies for marketing activities, and these Web sites are typically used only to broadcast information by providing brochure-like information. Others are more advanced and sophisticated in this regard, taking advantage of Web technologies to make business activities more effective and efficient, or even to reengineer whole business practices. More advanced DMO Web sites typically include more sophisticated capabilities, such as interactive queries and request forms, personalization, recommendation functions, streaming video, and interactive maps.

Web Advertising/Promotion

The Internet is an almost pure manifestation of marketing principles and practices (Inkpen 1998). It is a tourism marketer's dream because: (1) it enables travel companies of different sizes to compete on more equal terms, and (2) it allows a travel company to open up a direct and potentially personalized channel of communication with its customers. In other words, travel companies of all sizes are much more equal in their competition for consumers' attention on the Internet. Travel is the most important business on the Web in terms of the volume of advertising and promotion (eMarketer 1999). It is also most likely to generate revenues and achieve profits through its Web presence. However, in order to be successful in Web advertising/promotion, tourism organizations have realized that the Web is a medium that combines the elements of other media. Hoffman and Novak (1996) describe the new form of communication that the Internet provides as an "interactive multimedia many-to-many communication model," in which interactivity can be *with* the medium in addition to *through* the medium. Travel and tourism fit especially well with interactive media because they constitute an information-intensive industry in which transactions can be rather easily made online. The industry has therefore largely embraced new advertising techniques such as viral marketing, search-engine optimization, and cost-per-click advertising.

E-Commerce Activities

Before the onset of the Internet, electronic commerce was usually conducted over a proprietary network connecting a group of organizations such as airline companies, travel agents, and hotels through CRSs or GDSs. The nature of the transaction was purely business-to-business. Tourism businesses now use the Internet as a means of redefining their focus, creating new products, finding new distribution

channels, and creating new markets. For example, the major airline sites now offer customer reservations, electronic tickets, seat selection, in-flight merchandise, and reward points; in addition, some of the airlines have enhanced their sites to offer lodging, transportation-package deals, and cruises through their alliance partners.

The use of the Internet in the travel and tourism industry has also been driven by the convergent forces of the shift of consumer behavior toward more intensive uses of online environments and the successful adaptation of marketing and sales strategies by the industry. For many consumers, online booking of travel is already the norm, and this can only be expected to strengthen in the immediate future. Travel is a product that online consumers want to purchase; indeed, according to Forrester Research (1999), it is the product that those who are online, but have not yet purchased online, want to purchase most. From the point of view of travel and tourism suppliers, however, there is some reticence from certain sectors of the industry, such as cruise lines, to compete directly with their traditional intermediaries by making the move to direct sales, whereas others, such as airlines, have embraced the new online channels with great enthusiasm.

From an industry perspective, increased e-commerce activities have led to greater disintermediation and more direct contact with consumers. Traditional intermediaries (e.g., wholesalers, incoming agents, tour operators, travel agents) built up a distribution system characterized by complexity and cost. The widespread growth of the Internet is creating a more complex but efficient information and distribution system in which distribution is handled through a variety of channels. This includes more direct distribution, where the supplier, regardless of location, sells directly over the Internet to the consumer. Disintermediation will drive more responsive product offerings from suppliers and a greater focus on customer loyalty and retention. Distribution continues to involve intermediaries who offer advice, aggregation, and value-added customer services, but pricing has become more transparent, and distribution cost is often paid by the travelers rather than just by the suppliers. Such a complex distribution environment emphasizes the importance of yield and channel management not only for major tourism companies but for suppliers of all sizes.

E-commerce solutions are gaining momentum and are expanding beyond reservations to include supply-chain management (e.g., procurement), internal business applications through intranets, and other business-to-business transactions as well as business-to-customer sales. It is certain that the Internet will continue to become faster, more reliable and secure, and also more feature-rich. In addition, it will become more mobile through portable devices such as personal digital assistants (PDAs) and cell phones that can communicate with ambient intelligent devices embedded in appliances and will increasingly be enabled by speech, thus truly giving customers anytime, anywhere access in a format conducive to their needs.

Customer Relationship Management

Customer relationship management (CRM) is a managerial philosophy that calls for the reconfiguration of the travel organization's activities around the customer.

Successful CRM strategies evolve out of the ability to effectively capture exhaustive data about existing and potential customers, to profile them accurately, to identify their individual needs and idiosyncratic expectations, and to generate actionable customer knowledge that can be distributed for ad hoc use at the point of contact (Newell 2000). Further, the success of CRM initiatives is dependent on the ability to collect, store, and aggregate large amounts of customer information from various sources. One of the major driving forces of CRM using the Internet is the ability to target each individual interactively. With the Internet, individuals and travel marketers can interact, and this direct interaction creates customer value and sets the stage for relationship-building. Travel marketers continue to seek ways for compiling accurate databases of personal information such as sociodemographic, socioeconomic, geographic, and behavioral characteristics for potential customers. Such a database creates a wealth of relationship-marketing opportunities. Crucial to the establishment of such comprehensive customer databases is the ability to use software agents, without human intervention, to collect, categorize, and store large amounts of personal customer information in a cost-effective manner for later data mining. A second important issue is the ability to collect the desired information directly from the primary source rather than having to purchase it from secondary sources such as travel and tourism consultants. Nevertheless, many travel suppliers, notably airlines, have been slow in adopting or expanding CRM systems.

Online Destination Management Systems

The term *destination management system* (DMS) has come into use in recent years to describe the IT infrastructure of a DMO, and may be defined in a number of ways depending on the capabilities of the system. Increasingly, a DMS is regarded as having to support multiple functions. An integrated DMS supports not only the DMO's Web site, but also a wide range of other promotion, marketing, and sales applications (Sheldon 1997). These might include the design and production of printed materials, tourist information center services (for information and reservations), call-center services, kiosks, database marketing, project/event management, and marketing research. DMSs can greatly enhance a travel destination's Web presence by integrating information from various suppliers and intermediaries and are increasingly used as the informational and structural basis for regional Web portal sites. To date, only a minority of DMOs have invested in such integrated systems, and DMOs often have disparate technology platforms running a variety of applications. Investment in this area, however, is accelerating.

TRAVELERS AND THE INTERNET

Internet technologies have not only changed the structure of tourism and its related industries, but they have also had a profound impact on the way consumers search for tourism information, construct and share tourism experiences, and purchase tourism products and services. In contrast to many consumer goods and services, the consumption of tourism experiences involves often

Figure 2: Communication and information needs in the three stages of tourism consumption

extensive preconsumption and postconsumption stages, in addition to the actual trip, which itself can spread over several weeks (Jeng and Fesenmaier 2002; Moutinho 1987). These stages of the tourism consumption process are typically information-intensive, and Internet technologies have come to play a significant role in supporting consumers throughout this multistage process. The specific ways in which the various technologies are used in the different stages depend on the particular communication and information needs they are expected to serve (see Figure 2). For instance, Internet technologies are used in the preconsumption phase to obtain information necessary for planning trips, formulate correct expectations, and evaluate, compare, and select alternatives, as well as to communicate with the providers of tourism products and services to prepare or execute transactions. In contrast, the functions served by technologies during the actual consumption of tourism experiences are more related to being connected and to obtaining detailed information relevant to a specific place and moment in time. During the postconsumption phase, Internet technologies are used in ways that allow sharing, documenting, storing, and reliving tourism experiences, as well as establishing close relationships with places, attractions, or product/service providers, as in the case of Frequent Flyer programs. For example, e-mail will typically be used in all stages, but mainly to obtain information or make reservations in the preconsumption phase, to stay connected with family and friends while traveling, and to share pictures and stories with members of one's travel party or other individuals after concluding a trip. Although all Internet technologies are probably used by travelers at some point or in some way, several applications have been identified as being of particular importance in the context of tourism experiences. The following provides an overview of these technologies, how they tend to be used, and the impact they have on consumers during the various stages of the tourism consumption process.

Preconsumption

It is in the initial phase of the tourism consumption process that most of the impacts related to Internet-based technologies are currently experienced. Consumers use the Internet and its diverse applications in this first stage of the tourism experience to gather information, formulate expectations, inform/support their decision making, and reserve or purchase the various components (transportation, accommodation, etc.) to be consumed during their trips.

Brochureware

Brochureware refers to Web sites or Web pages created by transferring the contents of printed tourism brochures directly to digital environments. Brochureware was one of the first Internet applications made available to tourism consumers, owing to the fact that tourism businesses quickly recognized the value of the Internet as a powerful publishing medium. Web sites designed as brochureware represent the simplest form of Web design and completely ignore the content presentation and communication possibilities the World Wide Web offers (Hanson 2000). Nevertheless, brochureware is the most common way in which tourism information is currently made available to consumers and, consequently, constitutes an integral part of tourism-related online experiences. Despite their obvious limitations, digitized tourism brochures on the Internet still support consumers in that they enable potential travelers to browse and evaluate tourism products without temporal or spatial limitations. Furthermore, even the very basic implementations of brochureware make use of hypertext and provide hyperlinks that allow consumers to move through online tourism information in ways that are typically not supported by printed brochures. Brochureware is expected to give way to more interactive forms of Web-site content presentation as more and more tourism businesses recognize the value of engaging consumers in experiential ways.

Virtual Tours

Virtual tours are tools that enable the potential consumers of tourism products to explore and immerse themselves within an interactive Web environment in order to gain the needed experiential information about a destination or tourism establishment (Cho and Fesenmaier 2001). The term *virtual tour* is widely used on the Web, and can range from a series of pictures or a slide show to streaming video and highly interactive virtual reality settings. The realism provided through virtual tours creates immersion, which, in turn, leads to immediate, direct, and real experiences that generate a strong sense of presence. As a result of this telepresence experienced through virtual tours, consumers are able to construct a more vivid picture of the tourism product and are therefore more likely to reach well-informed decisions. Thus, the significance of virtual tours in the context of tourism lies in providing consumers with an opportunity for "product trial" before the actual purchase. Tourism products are, in large part, experience-oriented intangible goods (Vogt and Fesenmaier 1998) that are typically consumed at a place far away from the point of purchase and

often cannot be experienced without being consumed in their entirety. Consequently, product trial is usually not available to the potential consumers of tourism products. However, tourism bears many risks because its components are consumed in unfamiliar environments, constitute a significant expenditure for most consumers, and typically entail high involvement on the part of the consumer. Given the limited opportunity for pre-purchase trial in the context of tourism, virtual tours, with their ability to represent tourism products and services in more realistic and dynamic ways than other promotional materials, play a crucial role in offering rich travel information.

Travel-Decision-Support Systems

The term *travel-decision-support systems* (TDSS) refers to information systems designed to simplify the travel-decision-making process and support consumers in the various steps involved in planning trips. Trip planning is a very complex process that consists of a number of decisions, which often condition each other (Dellaert, Ettema, and Lindh 1998; Jeng and Fesenmaier 2002; Woodside and MacDonald 1994). Also, each decision requires different kinds of information; thus, separate information-search activities are necessary. This increases the cost of the information-search process for the consumer and can often lead to information overload (Good et al. 1999; Hibbard 1997). The main function of a TDSS is to identify and present certain tourism products and services in accordance with consumer preferences, thus reducing the number of alternatives that the consumer would have to evaluate. The functionality of such systems ranges from more sophisticated search engines and intelligent-agent-supported information retrieval to true recommendation systems that enable the consumer to identify destinations or tourism products of interest (Vanhof and Molderez 1994). The use of a TDSS generally requires specifying preferences such as desired date of travel and preferred activities. In their most advanced form, these systems try to mimic face-to-face human interactions that could occur between a consumer and a travel agent. In such cases, the TDSS is typically referred to as a "travel counseling system" (Hruschka and Mazanec 1990). Current developments in the TDSS area focus on increasing the ability of such systems to capture consumer preferences and adapt information accordingly, as well as to learn from past interactions and support group decision-making (Delgado and Davidson 2002; Hwang and Fesenmaier 2001; Loban 1997; Mitsche 2001; Ricci and Werthner 2001). Consumers can take advantage of such systems and benefit from the customized information presented to them at various stages in the trip-planning process. However, the currently available TDSS versions are still more capable of supporting consumers with a clear understanding of what they desire than helping individuals with only a vague idea of what they are looking for. It is expected that these systems will play an increasingly important role in travel planning as they become more human-centric in design and truly adaptive with respect to the needs of consumers (Gretzel, Hwang, and Fesenmaier 2006).

E-Commerce Applications

E-commerce applications are technologies that support online transactions between the providers and consumers of tourism products and services. Online reservation and payment options were quickly adopted by many suppliers and consumers and led to the emergence of tourism as one of the most important e-commerce categories. It can be argued that the reasons for this rapid adoption of e-commerce in tourism lie in the particular fit between the characteristics of tourism products and the capabilities of e-commerce applications. The purchase of tourism-related products and services typically involves the movement of information rather than the physical delivery of goods and is often concluded using credit-card payments. Also, the complex and strictly hierarchical tourism distribution system of pre-Internet times led to enormous information asymmetries and little choice for consumers in terms of where or how to acquire tourism products. With the introduction of e-commerce, consumers were provided with a new means of buying that they were eager to adopt because it not only offered more choices through direct links to the many geographically dispersed industry players or new intermediaries such as online travel agencies, but also catered to consumers by providing new levels of convenience. E-tickets, for example, are a direct result of e-commerce initiatives and have tremendously simplified travel, especially business travel. Current developments in the area of e-commerce focus primarily on raising security and privacy standards to ensure safe and smooth transactions. In addition, efforts are being undertaken to make a wider range of tourism products available online. Destination management systems are becoming more widespread and promise more extensive e-commerce adoption, thus providing consumers with greater access to an increasing variety of tourism products and services.

Online Customer Support

Online customer support is a summary term for Internet technologies that allow consumers to contact the suppliers or distributors of tourism products if additional information or other forms of assistance are needed. Applications that provide consumers with the means to communicate more quickly and more easily in order to get support are especially important in the context of tourism. First, the special nature of tourism products and services (see Kotler, Bowen, and Makens 1999 for a detailed description) makes them more likely to require additional support. It is very difficult to describe the many experiential aspects of tourism accurately; thus, consumers often require further interpretation or more detailed explanations. Also, tourism products and services are usually purchased or at least reserved long before they are consumed, and many things can potentially happen during this extensive period of commitment between travel- and tourism-related businesses and consumers.

Second, geographical and cultural distances between travel and tourism suppliers and consumers render communication through traditional means very difficult. The Internet, on the other hand, provides consumers with fast, easy, and cost-effective ways of contacting the providers of travel and tourism-related goods and services.

Technologies of support include "Frequently Asked Questions" sections on Web sites, online request forms, bulletin boards, Internet phones, e-mail, real-time chat options, and instant-messaging applications. These technologies are currently used in very passive ways, which means consumers are required to initiate the contact. However, a growing number of tourism organizations are adopting more proactive approaches to online customer support. They provide consumers with active assistance either through automatic e-mail updates or by monitoring the behavior of Web-site visitors and offering real-time assistance through instant messaging or chat if they recognize search or click patterns that are typically associated with a need for help, such as seemingly uncoordinated click-streams. This innovative use of online customer-support technologies actively encourages consumers to communicate with customer representatives and has the potential to prevent confusion or misunderstandings instead of following the traditional model of solving problems after they have occurred. This trend is driven by a recognition that personal communication can be more effective in resolving complaints and building customer loyalty.

During Consumption

Internet technologies are used during the actual trip mainly for travelers to stay connected and to obtain en route information if, and only if, the need arises. The spread of Internet cafés at tourist destinations, the growing number of accommodation establishments offering (often high-speed) Internet connections, and the recent efforts of airlines to provide in-flight Internet access to travelers indicate that a substantial need for these kinds of information and communication links exists. En route Internet access means anywhere-and-anytime availability of tourism-related information for consumers. Therefore, many of the trip-planning and information-gathering tasks of travelers could shift from preconsumption to during consumption and make travel much more spontaneous if the Internet becomes more widely available to the traveling public.

Mobile technologies play an increasingly important role in tourism due to their ability to provide travelers with wireless and, thus, instantaneous and pervasive Internet access. Handheld devices such as personal digital assistants (PDAs) and cellular phones supported through a wireless application protocol (WAP), a global system for mobile communication (GSM), and short message service (SMS) allow travelers to take full advantage of the Internet while on the road. More ambitious developments of mobile technology go beyond simple access by providing real-time location-based services (Eriksson 2002; Oertel, Steinmüller, and Kuom 2002). Empowered by geographical information systems (GIS) and global positioning system technology (GPS) in combination with information available on the Internet, these advanced mobile applications identify the traveler's location in space and the spatial context of this position. This information is then used to generate personalized assistance in the form of location-specific and time-sensitive information. Many advancements related to mobile

technologies are spurred by needs that directly arise from information and communication problems encountered during travel. Projects such as CRUMPET—creation of user-friendly mobile services personalized for tourism (Poslad et al. 2001; Schmidt-Belz, Makelainen, Nick, and Poslad 2002)—and the development of wireless-based tourism infrastructures (e.g., the ambient intelligence landscape described by the Information Society Technologies Advisory Group [ISTAG] [2001]), are two examples of the many efforts undertaken at the juncture of mobile technology and tourism, which represent developments with important implications for the future of the entire Internet.

Postconsumption

The postconsumption stage in the context of tourism involves treasuring souvenirs, remembering special moments, reliving an experience through photographs, sharing travel stories, and often developing a strong sense of attachment to a specific destination. Internet technologies play a significant role in these post-trip activities and have started to significantly influence memory practices as they relate to tourism.

Virtual communities are an example of Internet applications that provide consumers with support during the postconsumption phase. The term *virtual community* describes a group of people who are connected through computer-mediated communication technologies and share interests and feelings in cyberspace (Rheingold 1994). Virtual travel communities, then, are communities facilitated by computer-mediated communication that allow members to conduct various types of travel-related tasks, such as obtaining travel information, maintaining connections, finding travel companions, or simply having fun by telling each other interesting travel experiences and stories (Wang, Yu, and Fesenmaier 2002). Consumers can use these virtual travel communities to post photographs and stories/testimonials of their trip(s) on the community Web site, where they serve as information to other consumers. In addition to this purely functional aspect, virtual travel communities offer opportunities for members to fulfill hedonic, psychological, and social needs. A sense of belonging, fun, and self-identification are only a few of the benefits that can be derived from online community membership. In the context of tourism, the most important function virtual travel communities serve is the extension of travel/tourism-related experiences beyond the actual trip. Used as digital substitutes for traditional photo albums, the digital images uploaded onto community Web pages and discussion boards help recall aspects of trips and assist consumers in constructing memories of vacations. The travel stories and discussions that can be found in such communities mimic real-world storytelling activities typical of this last stage of the tourism consumption process.

Tourism experiences are an integral part of the collective memory of families and peer groups and, thus, require sharing. Consequently, consumer-generated media (CGM) have gained importance beyond the settings of virtual communities. In contrast to traditional conversations about the adventures, fun events, or other types of

memorable moments of past trips, communication about travel experiences in blogs, virtual communities, other discussion forums, and personal Web pages takes place with an audience that has a very tailored interest in the topic and often resides outside the boundaries of one's usual social circle. Also, the information posted by consumers in the course of the postconsumption recollection of the travel experience serves as valid information for consumers in earlier stages, thus closing the loop of the tourism information cycle. The information provided by other consumers is especially valuable, as it represents personal accounts of probably alike consumers with actual product knowledge and no commercial interests. Thus, CGM can serve as a vehicle to control the quality of travel products and services through consumers' evaluation and ratings of a wide range of travel products and services. However, increasing numbers of advertisers and tourism businesses are discovering CGM as particularly suitable vehicles to communicate messages to and establish relationships with specific target markets. For instance, most major online travel agencies have started soliciting and featuring such content, moving it into the mainstream as an important customer service. This has also led to a new recognition, long observed in mainstream media but seldom in the tourism sector, of the delineation between editorial and commercial content. Importantly, it has focused greater attention on travel content (of any type) being authentic, real, and credible.

Impacts of Internet Technology on Travel Behavior

The Internet has had and will continue to have a tremendous impact on the way consumers search for, purchase, consume, and remember tourism experiences. However, the Internet is not the only channel through which consumers obtain information, communicate, or complete transactions. Rather, it is one of many options currently used by tourism consumers. Word of mouth, for instance, remains the most popular way of gaining access to firsthand knowledge about travel destinations and tourism experiences. Also, travel magazines and movies continue to be significant sources of inspiration. It seems that the concept of the "hybrid" consumer, who uses many media and technologies simultaneously (Wind, Mahajan, and Gunther 2002) is especially applicable to tourism. Thus, the Internet has not replaced traditional channels but has placed additional options in the hands of consumers. Nevertheless, many current technology developments aim at convergence and the creation of one channel that can satisfy all information search, transaction, and communication needs; therefore, this situation might change in the near future.

In general, the Internet and its many different applications have provided consumers with an incredible number of choices, opportunities for comparison shopping, and much more control over many processes related to the consumption of tourism experiences. The success of auction models such as Priceline.com, where consumers name prices rather than accepting the industry-imposed price, indicates that the market has shifted from a supplier- to a consumer-dominated market.

Tourism has always been characterized by many alternatives. Yet many consumers lacked the necessary information to take advantage of the variety of tourism offers available. The Internet has, to a large extent, closed this information gap. Internet consumers are much more informed, and this new level of information and knowledge among "new" consumers has opened up many choices. The larger extent and different, more experiential nature of information available to consumers has also led to more accurate expectation formation and more informed decision making, both of which are especially important for the consumers of information-intensive, intangible, and high-involvement tourism products and services. On the one hand, the ease with which information can be made available online has placed an abundance of information at the disposal of consumers. On the other hand, it causes situations of severe information overload and leads to many concerns about trust. The Internet facilitates information representation and distribution; however, it also makes it more difficult for consumers to identify false information. Many tourism businesses are very small and operate thousands of miles away from where their customers live. It is, thus, extremely difficult for consumers to verify their existence, not to speak of the nature and quality of their business practices. Consequently, the consumers of travel- and tourism-related products can be expected to continue relying on offline and online intermediaries as well as official Web portals such as destination marketing sites to obtain reliable and trustworthy information about tourism establishments.

The Internet has increased the speed with which information moves between tourism suppliers and consumers, and many consumers have started to expect instantaneous information and support with respect to all aspects of their trips. The Internet has influenced not only perceptions of speed but also the extent of personalization expected by the consumers of tourism information and products. These new expectations in terms of speed and personalization spurred by the Internet represent an enormous challenge for the tourism industry and leave many consumers disappointed with the level of service they receive.

One of the main advantages of the Internet is that it provides consumers with the opportunity for anytime-and-anywhere access to information. Many aspects of a trip that had to be planned well in advance can now be finalized while on the road. Internet technologies that provide consumers with such en route access to information have the potential to significantly transform trip planning and influence travel patterns. Recent trends indicate that travel is in the process of becoming more spontaneous and that many travelers choose to travel to destinations that they would not traditionally have considered because of the high risk. One can only speculate about the impact of this trend on tourism in the Internet era, as extensive planning is an integral part of the tourism consumption process and careful preparation is often essential to the success of a trip (and sometimes even crucial to the survival of the travel party).

The advent of the Internet has brought about many dystopian fears related to the future of tourism. Many predicted the end of travel per se and pictured

tourism experiences as being confined to virtual-reality simulations. The future of tourism on the Internet from a utopian perspective of course looks much brighter. Such a perspective interprets Internet experiences as a substitute for travel and, thus, a great opportunity for individuals with disabilities or other constraints that limit them from traveling. Neither scenario has been realized so far. Internet technologies have discouraged some types of travel and encouraged others. The experiences presented on the Internet constitute far from real substitutes for actual travel, but they do provide invaluable information about accessibility and allow individuals with special needs to prepare more accurately for real-world trips. Consequently, when analyzing the influence of Internet technologies on consumer behavior in the context of tourism, one has to constantly remind oneself that the Internet is still in the process of becoming and that its impact on the consumers of travel and tourism products and services can be partly grasped but not yet fully understood.

TRAVEL AND TOURISM FUTURES

For the tourism industry, the Internet is clearly the biggest opportunity but simultaneously the biggest challenge. Looking to the future, of course, poses many questions; however, there are a number of general trends pointing in the direction of the future development of travel and tourism. In this section five technology-related trends will be considered: (1) the continuing speed and sophistication of information technology; (2) the continuing growth in the use and uses of information technology in tourism; (3) the changing forms of information technology as a medium for communication; (4) the emergence of a new tourism consumer; and (5) the emergence of experience as the foundation for defining tourism products. The following will identify and briefly discuss each trend, focusing attention on its impact on the tourism industry.

Trend # 1: The Continuing Speed and Sophistication of Information Technology

The personal computer celebrated its twenty-fifth birthday in 2006. In an article in *PC Magazine*, the personal computer (PC) was described as one of the most profound inventions in the history of mankind (Miller 2002). From its inception in 1981 the development of personal computer technology has been shown to follow Moore's law—that chip density, and therefore the speed of computers, will double every 18 months. Thus, computers and computer technology have grown from the very “primitive” Radio Shack TRS-80 and the IBM 4.7 MHz 64K RAM 8088 processor, an operating system called DOS, and software called VisiCalc and Wordstar to today's 3.8-GHz machines with up to 16 GB of RAM. Over the years, various competitors have infused the market with a variety of innovations focused on expanding the power of the machine and the ability of the system to address workplace needs and encouraging society to think/dream about what might be in the future (Miller 2002). As the systems grew more sophisticated and powerful and arguably more human-centric, the power of the network was recognized and spurred even greater innovation.

In 1990, the World Wide Web was born, along with a new generation of innovators seeking to build an information infrastructure that could enable individuals to collaborate from distant locations. The outcome was Mosaic and a decade of unparalleled innovation and “build out” in information infrastructure. This new orientation also led to the development of a variety of computer-enabled devices, such as cell phones and personal digital assistants, which are now beginning to pervade human society (Norman 1999).

A number of scholars have recently reflected on the progress of computer technology and have concluded that there is much to be accomplished before computers/information technologies can truly enable society to benefit from their power. In *The Unfinished Revolution*, Dertouzos (2001, 6) argued that “the real utility of computers, and the true value of the Information Revolution, still lie ahead.” He suggested that over the past twenty years society has evolved to “fit” around computers and that the productivity gains from computer technology have been “more hype than reality.” Supporting this argument, Norman (1999) suggested that the real benefits will be realized only when computer technology becomes more human-centered—that is, when technology adapts to the needs and lifestyles of human beings. They argue that information appliances—computer systems that focus on specific tasks and are connected through the Internet or wireless technology—are the basis of human-centric and thus “invisible” computing. It appears that the focus of emerging technology is on empowering the individual within the framework of the human experience rather than defining human behavior around the needs of computer designers.

Examples of emerging technology that is beginning to be used in the travel and tourism industry include online mapping technology, RSS (really simple syndication) feeds, podcasting, travel recommendation systems, virtual reality, and travel guidance systems. A number of basic recommendation systems are available in a variety of travel-related Web sites including Ski-europe.com, Travelocity.com, and TIScover.com. Indeed, virtual reality and related technologies are evolving sufficiently to enable travelers to sample/experience the destinations prior to the actual trip. In addition, global positioning system (GPS)-supported travel guidance systems, which once were considered exotic, are actively marketed for automobiles. Further, tools to map locations, RSS feeds of travel news and podcasts of walking tours are now available on some DMO Web sites and are expected to be widely adopted within the next couple of years.

Trend # 2: Continuing Growth in the Use and Uses of Information Technology in Tourism

The number of Internet users continues to grow worldwide and as a result, the Internet's potential as a marketing medium has expanded greatly and continues to expand. As of March 2006 71.5 percent of American adults, or about 144 million people, used the Internet, up from 66 percent the previous year. Of these Internet users, 83.6 percent had had Internet access for 4 years or more, indicating that Internet users had also become

more experienced (Pew Internet & American Life Project 2006). The worldwide Internet population was estimated at over 1 billion users in 2005 and is projected to reach 1.8 billion by 2010 (ClickZ.com 2005). The USC Annenberg School Center for the Digital Future (2005) reports that Internet use has been adopted across all segments of American society and that the Internet's importance as an information source is steadily increasing, with now 56 percent of adult Internet users considering it to be a very or extremely important source of information for them. The Digital Future Project survey further found that the number of hours spent online continues to grow, rising to an all-time high of on average 13.3 hours per week. More than two-thirds of home Internet users (70 percent) have high-speed Internet access (Pew Internet & American Life Project 2007, *Home Broadband Adoption*).

Looking for travel information is one of the Top 10 online activities of Internet users, with 73 percent of Internet users indicating that they have engaged in this activity (Pew Internet & American Life Project 2007, *Internet Activities*). TIA reports that online travel planners are more likely to be female, better educated, and married than those who do not plan and/or book travel online (TIA 2005). This most recent TIA study also shows that most (71 percent) of those planning trips online say they do at least half of their travel planning on the Internet. Further, the percentage of online travel planners who actually book or make travel reservations has increased significantly, to 82 percent of online travel planners or 64 percent of travelers with Internet access. Table 3 shows that airline tickets continue to be the travel product most frequently purchased online, followed by overnight accommodations and rental cars.

Table 3: Percent of Travel Products/Service Purchased Online in 2005 (among 64.8 Million U.S. Travelers Who Have Internet Access and Who Booked Travel Online)

Travel Products/Services	2004	2005
Airline ticket	55.6	55.6
Overnight lodging accommodations	46.3	49.4
Rental car or RV	27.3	26.2
Tickets—cultural event	16.0	20.7
Tickets—theme/amusement park	9.0	15.1
Travel package	9.4	13.6
Tickets—museum or festival	10.8	11.9
Tickets—spectator sporting event	7.6	11.1
Reservations for personal sports (like golf/skiing/water sports)	7.3	9.6
Tickets—tour or excursion	8.5	8.8
Cruise	5.7	7.1

Source: TIA (2005).

Trend # 3: Changing Forms of Information Technology as a Medium for Communication

Industry experts have increasingly questioned whether the Internet is different from other media and whether it needs to be addressed in new ways using new strategies (Godin 1999; Hoffman and Novak 1996; Zeff and Aronson 1999). The Internet is special in that both consumers and firms can interact with the medium, provide content to the medium, communicate one to one or one to many, and have more direct control over the way they communicate than using other media. When everyone can communicate with everyone else, not only the old communication models become obsolete but so do the communication channels that are based on them (Evans and Wurster 1999).

In contrast to traditional media, the Internet combines and integrates the following functional properties: (1) information representation; (2) collaboration; (3) communication; (4) interactivity; and (5) transactions. As a consequence, Internet communication can be much more holistic than communication through traditional media. The Internet can simultaneously integrate informational, educational, entertainment, and sales aspects; this flexibility makes the Internet rich and appealing but also very complex and difficult to deal with. Interactive media such as the Internet build the foundation for interactive marketing: "The essence of interactive marketing is the use of information *from* the customer rather than *about* the customer" (Day 1998, 47). It differs from traditional marketing because it is based on dialogue instead of one-way communication, and it deals with individual consumers instead of mass markets (Parsons, Zeisser, and Waitman 1998). Using these capabilities of the Internet may lead to deeper relationships with customers and greater personalization of goods and services. Travel and tourism fit especially well with this interactivity aspect of the Internet because they are an information-intensive and experience-based industry.

Network technologies enable travel and tourism organizations to blend together publishing, real-time communication, broadcast, and narrowcast (Hoffman, Novak, and Chatterjee 1995). It is a medium that attracts attention and creates a sense of community. It is a personal medium, an interactive medium, and a niche and a mass medium at the same time (Schwartz 1998). In contrast to traditional media, the trade-off between richness and reach is not applicable to the Web. Evans and Wurster (1999) define *richness* as the quality of the information presented (accuracy, bandwidth, currency, customization, interactivity, relevance, security). *Reach* refers to the number of people who participate in the sharing of that information. The trade-off between richness and reach leads to asymmetries of information. Thus, when DMOs are able to distribute and exchange rich information without constraint, "the channel choices for marketers, the inefficiencies of consumer search, the hierarchical structure of supply chains, the organizational pyramid, asymmetries of information, and the boundaries of the corporation itself will all be thrown into question" (Evans and Wurster 1999, 37).

Part of this trend will also be the development of mobile electronic devices and networks that will more

effectively distribute complex travel content to travelers. Such applications will include GPS-enabled content, complex search capabilities; rich media, including video and mapping, plus real-time pricing and booking functionality. A series of network technology applications such as third-generation (3G) mobile networks and improved satellite coverage are now enabling the distribution of such rich content. With increasing usability and ever lower prices, it is expected that such technologies will be widely adopted and will increase consumers' expectations regarding the richness and relevance of information accessible to them.

Trend # 4: Emergence of a New Tourism Consumer

The Internet changes how people communicate and exchange information. The resulting abundance of information and ease of communication have led to profound changes in consumer attitudes and behavior. What makes new consumers "new" is that they are empowered by the Internet, which provides them with easy and cheap access to various information sources and extended communities (Windham and Orton 2000). New tourism consumers are well informed, are used to having many choices, expect speed, and use technologies to overcome the physical constraints of bodies and borders (Poon 1993). Lewis and Bridger (2000) describe the new consumer as being: (1) individualistic, (2) involved, (3) independent, and (4) informed. The Internet is a highly personalized medium, and new consumers expect marketers to address and cater to their complex personal preferences. Consequently, new tourism consumers are "in control" and have become important players in the process of creating and shaping brands.

New tourism consumers are also very independent in making consumption decisions but, at the same time, like to share stories about their travel experiences with members of different communities. Stories can convey emotional aspects of experiences and product/service qualities that are generally hard to express in writing and, consequently, are rarely included in traditional product descriptions. Storytelling is an important means of creating and maintaining communities (Muniz and O'Guinn 2000), and Internet technologies greatly facilitate this form of communication and community building among travelers through new technologies such as blogs and social networking applications. Importantly, the new scarcities of time and trust require new tourism consumers to rely heavily on word of mouth and the expert opinions of like-minded others. New travel-oriented communities are brand communities or communities of interest and are imagined, involve limited liability, and focus on a specific consumption practice (Muniz and O'Guinn 2000; Wang et al. 2002). Travelers in this networked world are expected to increasingly take advantage of (or contribute) to consumer-driven content—sharing their experiences or advice with others—across the Internet's global community. This will greatly empower consumers and will force travel product suppliers to strive for excellence. It will also challenge grand narratives constructed by the media and large travel companies and will give

consumers an opportunity to construct knowledge about a destination or product offering from a great number of diverse sources. In addition, this trend will likely change host-guest interactions, as the new consumers increasingly seek contact with the locals through these new forms of networked communication.

At the same time, a wealth of information creates a poverty of attention (Lewis and Bridger 2000). New tourism consumers try to cope with this problem by scanning information depending on personal relevance and have become very capable of ignoring nonrelevant advertising. They are, therefore, much more active in their travel information search than old consumers, who were largely passive information recipients. Attention is increasingly reserved for marketers who have asked for permission and have established a long-term relationship with the consumer (Godin 1999). In return for his/her valuable attention, the new tourism consumer expects special benefits such as extremely personalized services. Attention peaks when these travelers reach a psychologically balanced state of mind, a so-called flow experience (Feather 2000). In order to reach flow, new tourism consumers are increasingly searching for personalized, emotional, and intriguing experiences through which they can learn about new travel and tourism products. Therefore, in the world of the new tourism consumer, the focus shifts from product attributes to consumption experiences.

Trend # 5: Emergence of Experience as the Foundation for Defining Tourism Products

It has long been recognized that travel is an experience and that tourism is a key part of the "experience industry" (Pine, Gilmore, and Pine 1999). However, the role of experience in consumption (including prepurchase, during purchase, and postpurchase) is only now being considered as one of the foundations for effective marketing. Research efforts have shown that the experiential aspects of products and services provide the starting point for effective marketing (O'Sullivan and Spangler 1998; Pine et al. 1999; Schmitt 1999). This research indicates that experiences are personal "events" that engage the individual in a meaningful way. As shown in Figure 3, the core element of travel experiences is the travel activity, whereas the tourism industry plays the part of an experience "facilitator"; importantly, the setting (social or personal) in which activities occur contributes substantially to the nature of the experience. It has been suggested that although the experiential aspects of travel are the foundation, the memories that are stored as a result of these experiences are the key to attracting new visitors as well as retaining current ones. Furthermore, it is suggested that stories—the mechanisms for communicating experiences through word of mouth or as "documentaries" of experiences (through articles, film, etc.) provide the path through which the tourism industry can build and extend markets.

Schmitt (1999) and others have argued that the new consumer evaluates products more on their experiential aspects than on "objective" features such as price and availability and that experiential marketing should focus on the experiential aspects that make the consumption

Figure 3: Sequence of travel experience

of the product most compelling—that is, the five senses. Effective experiential marketing is sensory and affective. It approaches consumption as a holistic experience and acknowledges that consumers can be either rational or emotional or both at the same time. Whereas traditional marketing is based on consumer behavior, product features, benefits, and quantifiable market segments, experiential marketing is driven by an understanding of consumer experiences and the need for personalization. New consumers require advertising that is entertaining, stimulating, and at the same time informative. Brands are no longer seen as mere identifiers but become themselves sources of experiences by evoking sensory, affective, creative, and lifestyle-related associations (Schmitt 1999). Thus, experiential marketing blurs the border between advertising, purchase, and use as it attempts to create a unique shopping experience and lets the new consumer anticipate what the consumption experience will be like.

CONCLUSION AND IMPLICATIONS FOR NETWORK TECHNOLOGY APPLICATIONS IN TOURISM

The Internet and emerging network technologies have had a profound impact on the tourism industry. The following briefly summarizes some expectations for the future role of these technologies in travel and tourism.

- Travel will continue to be one of the most popular online interests of consumers. This trend will increase in magnitude as travel providers create more effective means by which to communicate the nature of their offerings.
- The Internet and mobile communication devices are increasing the number of electronic connections between customers and the tourism industry. These new technologies will continue to provide an environment for creating relationships, allowing consumers to access information more efficiently, conducting transactions, and interacting electronically with businesses and suppliers. Examples of emerging technology in the travel industry include travel recommendation systems, travel guidance systems, and virtual reality.
- The changes in demographic profiles of Internet users over the past decade suggest that the evolving Internet and related systems will ultimately be adopted by the

large majority of the traveling public and, therefore, the Internet will be considered the primary source for travel information.

- The demands of travelers, and in particular the purchase process(es) they use, will continue to evolve as consumers of travel products gain more experience and confidence in purchasing products over the Internet. Importantly, conversations among travelers (through travel clubs, virtual communities, etc.) will continue to grow and will increasingly be mediated through network technologies.
- Experience- and emotion-oriented communications will grow in importance as human-centric computing and emotionally intelligent interfaces are offered. These interfaces/systems will incorporate a variety of interpreted information, enabling the systems to recognize the information needs of the user within an emotional-psychological need context, in order to provide supportive interactions and suggestions.
- Blogging, podcasting, and social-networking technologies are expected to play an ever more important role in supporting travel-planning activities as well as the construction of memories and extended experiences in the postconsumption phase of travel. It is expected that there will be an increasing need to integrate such applications on tourism and travel Web sites.

As individuals become more mobile and also more reliant on network technologies, they will increasingly demand systems that can support their lifestyle during trips. Travelers will expect to be able to enjoy the same level of technology use on the road as they do at home. This means that systems have to become truly portable/wearable, wireless, global, integrated, and smart. Indeed, museums and hotel rooms provide ideal test-beds for networked applications such as ambient intelligence because of their limited range of user activities and their relatively small scale. Also, they can potentially serve as catalysts for the adoption of specific technologies, as they have the ability to expose applications to a significant number of potential users. Finally, increasing competition in the travel and tourism industry will force businesses to cooperate even more. Thus, the need for high-speed, reliable computer networking technology will not only be pushed by consumer needs but will also be driven by industry demands.

GLOSSARY

Bloggng: The activity of writing entries to, adding content to, or maintaining a Web log (blog). A blog is an online publication with regular posts presented in reverse-chronological order.

Central Reservation System (CRS): A system that provides access to information about airline, hotel, or rental company inventories and is used for sales, marketing, and ticketing purposes. The elements of a CRS include a central processing unit, a central database, and a communications network that links information providers and users to the central information storage and processing system.

Consumer-Generated Media (CGM): Opinions, experiences, advice, or commentary related to products, companies, or destinations generated by consumers in the form of text, photos, and audio or video files and posted in product review sections on Web sites, blogs, virtual communities, discussion boards, etc.

Customer Relationship Management (CRM): A set of business principles with the aim of strengthening a tourism organization's relationships with its clients, optimizing customer service levels, and obtaining customer information that can be used for marketing purposes.

Destination-Management System (DMS): The information technology infrastructure used by destination marketing organizations to support a wide range of promotion, sales, and advertising efforts. Typical elements of such systems are technologies to design and produce printed materials, tourist information center services (including information and reservation systems), call-center services, kiosks, database marketing applications, project/event management software, and marketing research applications.

Destination Marketing Organization (DMO): An organization with responsibility for marketing a specific tourism destination to the travel trade and to individual travelers.

Distribution Channel: A set of interdependent organizations, such as tour operators or travel agents, involved in the process of making tourism products or services available to consumers.

En Route Information: Information obtained while traveling, as opposed to information collected before or after the trip; mainly used for navigational purposes or to support short-term decision making during the actual vacation.

Flow: A seamless, intrinsically enjoyable, self-reinforcing, and captivating psychological experience occurring when there is an optimal match between the challenge at hand and one's skills.

Global Distribution System (GDS): A system that links several central reservation systems, thus providing much more global coverage than individual computerized reservation systems.

Human-Centric Computing: The process of designing, developing, and implementing information technology that reflects the needs and lifestyles of its human users.

Intermediary: A third-party organization such as a travel agent, tour operator, incoming agent, hotel chain, or CRS/GDS provider that facilitates information transfer

and/or transactions between the primary suppliers and consumers of tourism products and services.

Podcasting: A term used to refer to the technologies used for automatically distributing audio and video programs over the Internet.

Telepresence: A mental state in which a user feels physically present within a remote, computer-mediated environment.

Tourism Experience: The sum of sensory, cognitive, and emotional inputs derived from the activities pursued during a vacation.

Travel and Tourism Industry: The individuals and organizations that are involved in the production and distribution of travel and tourism-related products.

Travel Decision Support System (TDSS): An information system designed to simplify the travel decision-making process and support consumers in the various steps involved in planning trips.

Virtual Travel Community: A community facilitated by computer-mediated communication that allows its members to conduct various types of travel-related tasks, such as obtaining travel information, maintaining connections, finding travel companions, or simply having fun by telling each other interesting stories about travel experiences.

Virtual Tour: A tool that enables the potential consumers of tourism products to explore and immerse themselves within an interactive Web environment in order to gain the needed experiential information about a destination or tourism establishment.

Yield-Management System: Powerful computer system using advanced mathematical modeling and predictive algorithms that manage pricing and availability information for tourism companies including airlines, hotels, and attractions.

INTRODUCTION

Web-based training (WBT) is learning at a distance using online training methods and delivery technologies. WBT is a subset of distance education, providing current content, adaptable and flexible access, and collaboration and interaction opportunities with other learners, tutors, and knowledge sources, potentially worldwide. Mobile learning (m-learning), the use of portable computing and communications devices, and pervasive computing, in which all aspects of a job or work environment are interconnected, are outgrowths of WBT (Leiner et al. 2002; Mobile learning 2004). WBT is grounded in the proven capacity of well-designed and well-moderated computer-mediated communications (CMC) to create and sustain effective collaborative and cooperative learning environments at a distance (Fulford and Zhang 1993; Rose 2004; Giguere, Formica, and Harding 2004).

Another key to WBT is the World Wide Web (www). The Web was at least occasionally available to 45 percent of the world's population in 2003 (OECD 2005), and in 2006 over a billion people were regarded as "Internet users" (Internet usage statistics 2006). The "digital divide" (between technology haves and have-nots) was even disappearing, according to some observers, early in the twenty-first century (Rupley 2005; Cheap tricks 2005).

The story of WBT is not without its ups and downs, however: the Web as a training tool has had both spectacular successes and disasters. While institutions such as the University of Phoenix, Concord Law School, the University of Monterey, and Canada's Athabasca University were successfully using online methods to offer courses throughout North and Latin America and Mexico, others (Columbia, Wharton School, Temple University, and NYU) were experiencing expensive failures with WBT (Higher Education Inc. 2005).

The theme of this chapter is that, as a training tool, the Web is potentially powerful, providing access to flexible, timely, relevant, and interpersonally satisfying collaborative training opportunities, including superior content learning and a sense of membership in an online community (Hiltz, Johnson, and Rabke 1980; Rovai and Barnum 2003; Fahy 2004; Conrad 2005). Wherever flexible training and professional development (PD) are central to organizations or nations, WBT can offer access to upgrading, training, retraining, and varied lifelong

learning opportunities. Accompanying WBT's strengths, however, are potential challenges or outright shortcomings (Dede 1996; Barns' storming 2005).

Potential advantages of WBT include:

- WBT is available anyplace and anytime, reducing time and travel-subsistence costs, and increasing learner control (Kaye 1989; Wagner, 1994; Bates 1995; Harapniuk, Montgomerie, and Torgerson 1998; Rovai and Barnum 2003; Don't take my PC 2004).
- Skillful e-moderating and instructing strategies can produce an interpersonal experience equal, or even superior, to face-to-face learning, especially when traditional courses are crowded or instructors overworked (Walther 1996).
- Centrally stored materials can be continually and immediately revised and updated, ensuring accuracy and currency.
- Use of markup languages (HTML, XML, SGML), and other interoperability provisions that are part of the Web's history of openness, ensure cross-platform compatibility.

Challenges of WBT include:

- Training materials must be carefully designed, or redesigned, for Web delivery; a sometimes substantial initial investment may have to be made in equipment and training (including potentially costly content managements systems [CMSs] and learning management systems [LMSs]); and trainees and instructors may have to learn new technical (and teaching-learning) skills (Welsch 2002).
- Structure must be provided in the learning environment to prevent users from wasting time, or straying into misinformation (Warren et al. 1996). The concept of e-moderating, the use of online methods for assessing and responding to trainees' needs for guidance, feedback, motivation, and human contact, arises from the fact that users do not always or automatically use WBT technologies skillfully or willingly.
- Bandwidth and technical limitations may restrict or even prohibit access to some Web resources.
- Dropout rates may be a problem in WBT, if users' problems are not monitored and addressed.

In this chapter, the history, characteristics, potentials, and challenges of WBT will be reviewed. Included will be a discussion of some important underlying general training principles critical to the evolution of WBT, the Web's strengths and limitations for delivering learning opportunities, features (and limitations) of some of the technologies WBT draws upon, and future prospects of WBT.

FUNDAMENTAL TRAINING PRINCIPLES AND WBT

In the first half of the twentieth century, the pioneering work of researchers such as Thorndike (1971), Dewey (1938), Skinner (1971), and Keller (1968) led to the articulation of fundamental learning principles. (These individuals researched and wrote in the fields of psychology and education, but their theories have been incorporated into the design of effective teaching of all kinds, including WBT.)

Thorndike's three fundamental behavioral laws, now common in WBT, were among the first to be stated: (1) repetition strengthens new behaviors; (2) reward associated with a particular behavior increases the likelihood it will be repeated, while punishment or lack of reward diminishes the likelihood of recurrence; and (3) individuals often differ in their personal readiness to perform a new skill or behavior (Saettler 1990).

Dewey added that individual trainee differences were crucial in the success of training. He and Piaget (1952) both recognized the importance of each individual learner's personal background, and advocated that trainees' experiences and previous learning be considered carefully and accommodated as much as possible in any new training situation.

Skinner applied and extended behavioral principles, with the "teaching machines" movement of the 1950s and 1960s. In behavioral psychology, the trainer was "the manager of the contingencies of reinforcement" in the learning process. Besides describing the instructor's role in a new way, Skinner's work illustrated points vital to the subsequent development of technology-based training, including the value of "the program over the hardware," and the critical importance of the learning materials and the organization of the learning environment (Saettler 1990).

Keller's Individually Programmed Instruction (IPI) model applied Skinner's discoveries about the importance of instructional design. The IPI model (called the "Keller Plan") emphasized individual differences in instruction and evaluation, including principles, later core to WBT, such as self-pacing, mastery before advancement, high-quality materials, tutoring help, prompt feedback, and careful and frequent evaluation, including practice testing (Fox 2002). Experiments such as teaching Morse code to World War II recruits demonstrated convincingly that these principles could dramatically increase the efficiency of procedural and skill training.

Innovations such as IPI were impressive, but they encountered organizational resistance for several significant reasons that are relevant to WBT:

- As innovations, technology-based training models often make new demands on institutions, trainers,

and trainees. In particular, technology-based training delivery increases the responsibility of trainees for their own learning, while limiting instructors' "platform" opportunities, serious flaws in the eyes of some trainers (and some trainees).

- Evaluations of technological innovations may initially yield "no significant difference" findings (www.nosignificantdifference.org); time may be needed to reveal their true value.
- Tepid managerial support may doom a technological innovation, especially if time and resources to prove its actual potential are in any way lacking.
- Individualized training models usually require more advance planning and preparation, while (at least initially) increasing workloads on instructors and administrators, and resource demands on programs, and while sometimes destabilizing programs during the adjustment phase.
- When granted responsibility for managing their own learning, some trainees may respond with demands for more individual treatment, including remedial and accelerated options. Overall, in individualized programs, including WBT, trainees expect their individual performance, needs, and preferences to be acknowledged and better met than in typical in face-to-face group training.

In the 1960s and 1970s, continued developments in instructional design, emerging consensus about "best practices" in adult learning, advances in cognitive and behavioral psychology, and new tools and approaches for the design and delivery of training converged to impact the emerging field of technology-based training and WBT. Other figures whose work influenced the evolution of technology-based training include Mager (1975), Suppes (1978), Glaser (1978), Gagne and Briggs (1979), Briggs and Wager (1981), and Dick and Carey (1978).

ASPECTS OF THE WEB AS A TRAINING TOOL

WBT's Payoffs and Demands

The Web emerged as a potentially powerful training tool, as training was transformed by new understandings of learning itself, and appreciation increased of the needs of trainees and training organizations (Biesenbach-Lucas 2004; Biuk-Aghai and Simoff 2004; Burbules and Callister 1998; Garrison, Anderson, and Archer 2000). Users responded to the Web's training potential differently, at least in part according to their appreciation of the importance of skill-training. Table 1 shows the range of possible engagement in training, from initial awareness to maintenance of a systematic training effort.

The potential of WBT to address critical training needs comes with costs, in the form of challenges to instructors and learners: different roles and responsibilities, changes in teaching methods and the learning environment, emphasis on individual differences, new financial and economic realities, and unprecedented security requirements.

Table 1: Employer Training Engagement Continuum

Stage 1	Stage 2	Stage 3	Stage 4	Stage 5
Gaining awareness of the general importance of skills	Recognizing and understanding the significance to their own organization	Making choices—to act or not to act?	Taking action—involving Sector Councils	Maintaining or increasing the training effort

Reprinted from Conference Board of Canada (2005, 3). Used with permission.

New Roles, Practices, Tools

Web-based training creates changes in the ways trainees interact with the trainer, the content, each other, and the learning system (Moore 1989). Because WBT allows shifting of place and pace of learning, roles change; the focus is on the trainees' skill development, and the tutor or trainer consequently becomes less the "sage on the stage" and more a "guide on the side" (Burge and Roberts 1993). Similarly, if permitted, equipped, and disposed to do so, trainees may assume more responsibility for their own learning, including accessing outside materials, communicating freely with the trainer, and collaborating with other trainees. Overall, successful WBT programs change trainees' experiences, providing greater individualization; making feasible self-pacing, on-demand review, acceleration, and practice testing; and providing ready linkages to a range of people and resources (Molinari 2004).

Because of the differences between online and traditional delivery, trainers in Web-based environments may find their duties and priorities changed. A study by the National Education Association (2000) of U.S. college instructors in a variety of institutions found that:

- Most reported WBT was more personally rewarding than traditional methods: distance methods were seen as giving trainees better access to information, better-quality materials, more help in mastering the subject matter, and more allowance for individual needs.
- Most instructors had at least some one-on-one contact with their Web-based learners, and those who had such contact reported higher levels of satisfaction.
- WBT required more instructor time, which, unfortunately, most training organizations did not formally recognize.
- Despite lack of organizational recognition of the greater time required, almost three-quarters of the survey respondents held positive feelings about distance teaching (14 percent reported negative feelings).

Materials and Instructional Activities

In traditional face-to-face teaching, instructional materials may be prepared at the last minute, or even simply dispensed with (trainees being required to take notes from the comments and chalkboard musings of the instructor). In WBT, materials preparation is a major stage in program development. Complete WBT materials are self-contained, including organizers and instructions, with guidance and feedback provided through embedded questions and other self-evaluation activities, and

computer-mediated communications (CMC) with the instructor and other learners. Support and orientation are provided for the technologies used.

In well-designed and well-managed WBT, instructional activities and materials may use some or all of the following principles:

- Typically, a wider range of resources, some from outside the local environment (accessed via the Web)
- Experiential learning and simulations
- Collaboration replacing competition (Collins and Berge 1996).
- Problem- or case-based learning, increasing training's realism and authenticity (students are permitted, even urged, to refine questions and objectives themselves, without constant reliance on the trainer) (Berge 1995).
- Personal knowledge and experience valued and included in problem-solving activities (Newby et al. 2000).

Multimedia are sometimes used to enhance WBT experiences; the impact of multimedia ultimately depends on recognition of certain design principles that govern their impact (Mayer 2001). These principles underscore the importance of systematic design and monitoring of WBT. Failure to produce instructional materials based on sound learning principles results in, among other errors, the amateurish use of effects for their own sake (contemptuously called "dancing baloney" by Web professionals) (HIP 2000, 2000). Failure to monitor learners' responses results in greater transactional distance in the learning environment (Moore 1991), potentially leading to alienation and, in the worst cases, dropout (Frankola 2001).

New tools, such as blogs and podcasting, allow instructors and trainees to develop and "broadcast" (via Internet RSS feeds) audio programs on any subject, downloadable to portable devices (iPods) or PCs. These are examples of how technologies offer new possibilities for delivery of training, and, because of their ready availability, make sound instructional design in serious training programs even more important (Magid 2005, DIY).

"Best" Instructional Practices in WBT

Well-designed WBT incorporates specific strategies known to enhance learning. One training model recommends that trainers strive for a balance between interpersonal rapport and intellectual excitement, requiring the trainer to be interpersonally warm, open, reliable, and

learner-centered, while also being clear and enthusiastic about the training content (Lowman 1994).

Another well-respected model suggests the following best instructional practices, applicable to WBT (Chickering and Gamson 1989):

- Encourage contacts between trainees and instructors.
- Develop reciprocity and cooperation among trainees.
- Use active learning techniques.
- Give proper and timely feedback.
- Emphasize time-on-task.
- Communicate high expectations.
- Respect diverse talents and ways of learning.

Bloom's (1984) classic description of the "alterable variables" of learning also provides guidance for Web-based developers and trainers. Research in mastery learning showed that the following principles, when emphasized, produced learning outcomes similar to what could be achieved under ideal training conditions (defined as one-to-one tutorials):

- Provide well-designed tutorial instruction.
- Give timely reinforcement.
- Give appropriate and sensitive corrective feedback.
- Provide cues and explanations, as needed.
- Encourage learner participation.
- Assure trainees make effective use of time on task.
- Help trainees improve reading and study skills, as required.

In general, adult education pedagogical principles of relevance, immediacy, learner control, autonomy, self-direction, self-pacing, and individualization are core to WBT practice (Kidd 1973; Knowles 1978; Cross 1981). One of the major differences between Web-based and more traditional forms of training is WBT's capacity for accommodating the individual expectations and preferences of trainees. This feature can be particularly valuable in meeting diagnosed "special" needs, or needs based on adult trainees' personal and situational variables. Personal variables include age, maturity, personal health, time availability (and management skills), motivation, previous learning, financial circumstances, and life and developmental stages. Situational variables include location (related to the location of any required site-based training), admission and training program requirements, availability of counseling and advisement services, and personal issues such as transportation, health, and child-care (Cross 1981).

WBT's capacity to accommodate differences effectively partially depends on the trainees' capacity and willingness to exercise independence, autonomy, and self-direction. Even if trainees are mature adults, the presence of the needed skills and confidence for self-directed learning cannot always be assumed. Trainees must be able and willing to exercise self-direction and independence in learning.

The needs analysis component of the design process is particularly critical, as problems can arise in WBT situations when there is a mismatch between the

self-direction the learning system permits or requires and the expectations of the trainees. As previously noted, mismatches between teaching or training style and learning style can result in dissatisfaction with the learning experience, or worse (alienation, failure, dropout). Programs are more successful if aligned with the developmental stages of individual learners. Trainee readiness may range from nearly complete dependency to autonomous self-direction, requiring the trainer to function variously as an authority or coach, a motivator or guide, a facilitator or mentor, and, at the highest levels of self-direction, a consultant (Grow 1991). Failure to provide learning conditions compatible with trainees' expectations for support, interaction, or recognition may be one of the principal reasons for unacceptably high dropout rates in some WBT programs (Frankola 2001).

Economic Factors

The economics of WBT, though changing rapidly in the details, continue to directly impact training providers and consumers.

For Providers

Skills requirements continue to increase, motivating employers to retain proven employees with the potential to grow with the expectations of their jobs (see Figure 1).

While the economic argument for training is strong, costs of development of WBT can be considerable, and vary dramatically. Primarily text-based WBT, involving conversion of existing materials using one of the many available authoring tools, may be economically accomplished by a subject-matter expert (SME) possessing basic instructional design skills. On the other hand, development of 1 hour of computer-assisted learning (CAL) using high-level authoring languages might require up to 150 hours of design and programming (Szabo 1998). Financial considerations are primary in most WBT implementations: if an organization cannot afford the attendant costs (especially the often heavy initial investment in development), it may not be able to make the transition to WBT, even if the need is clear and the organization willing (Welsch 2002). Bates (2000) argues cogently that costs and accessibility are the two governing criteria in the successful adoption of technology; the same could reasonably be argued for WBT.

WBT must be promoted realistically, without overselling the possible benefits or impacts. Although WBT offers the potential for substantial increases in convenience and improvements in efficiency (including reduced training costs), it is important to acknowledge that results of WBT cannot be guaranteed to be better for all users. This is because of interactions among economic, technical, personal, organizational, and environmental factors. One of the paradoxes of the past decade's use of technology generally, including training applications, has been the persistent finding of "no significant difference" in training results, accompanied by the "productivity paradox," the failure of some industries to achieve economic benefits from technology implementations, while others made impressive performance gains (Fahy 1998). Nevertheless, when design converges advantageously with needs,

opportunities, and a willing corporate culture, WBT has proven both successful and cost-effective (Welsch 2002).

For Trainees

Just as employers have seen the value of trained and skilled employees increase, employees are also aware that their prospects are directly related to their skills, as shown in Figure 2.

As they have become increasingly aware of the need for personal skill training, employees have also come to expect that the workplace will provide timely,

economical, high-quality, self-paced training, virtually anytime and anywhere (Vaas 2001). The keys to meeting these expectations are the cost and accessibility of the WBT technologies used (Bates 2000), and the relevance of WBT's interaction capabilities with respect to specific training applications (Fischer 1997; Inculcating culture 2006).

For trainees with "special" learning needs, WBT's interaction capabilities can provide important advantages. The mobility-handicapped, and those with learning disabilities, often find an environment with more learner

controls, typical of WBT, helpful (Keller 1999). Two core features of WBT directly applicable to special-needs trainees include:

- Structure, including advance organizers; clearly stated objectives, schedules, and timelines; embedded comprehension checks; integrated media under learner control; multimodal presentations; user-accessible performance records and reports; and communication links with the trainer and other support resources.
- Flexibility—any place, any pace access.

Trainers working with special-needs audiences must have enhanced capabilities to monitor progress, including easy communications with other helpers and supports. Trainees without special needs can also benefit from features of WBT, as these can potentially increase satisfaction and lower stress in general by reducing potential conflicts between the demands of training and participants' careers and personal lives. WBT's emphasis on interaction may help address:

- Feelings of inadequacy at the sheer amount of material to be covered.
- Delays in receiving feedback or answers to questions.
- Keeping up with the variety of discussions and interaction often present in online (computer-mediated communications, or CMC) discussions.
- Adjusting to the absence of visual cues in group relations.
- Fatigue and health problems arising from reliance on unfamiliar technologies (eye strain or posture problems at the computer, for example).

Security Issues

System and Personal Security

Security is a critical element of Web-based systems in general, and of training systems in particular, especially wireless systems. By one estimate, malware of all kinds caused \$55 billion in losses to Web users in 2003. Since 2003, damaging and hard-to-detect worms and Trojan horses have become the most common forms of malicious code. The threat is increasing: the virus-to-e-mail ratio was expected to go from 1 in 700 in 2000, to 1 in 2 by 2013; spyware has also become more prevalent and potentially damaging (Outbreak 2001; Airborne outbreak 2005).

In addition to protecting itself, a WBT training technology must also provide security for its users. Confirming and safeguarding the identities of trainees is a special problem in WBT, especially if they do not routinely meet face to face with instructors. Just as failure of a security system might expose a training organization to embarrassment, expensive down time, or even litigation, failure of an organization's screening and monitoring systems leading to a fraudulent registration, award of credit, or granting of a credential might be disastrous for its reputation. Biometric and other devices may make checking identities of trainees, supervising remote testing events, and blocking spyware (thus protecting the records and

identities of participants) more practical and economical (Buderi 2005; Talbot 2006).

PRESENT AND FUTURE PROSPECTS OF WBT

While WBT has proven its potential value for training delivery, some barriers continue to restrict or slow its expansion and impact its uses in complex training environments. These barriers arise chiefly in relation to bandwidth availability, user access to and adoption of required technologies (especially for m-learning), and user activity (especially unproductive and addictive behavior). Major opportunities lie in mobile learning and pervasive computing.

Bandwidth and Access

Broadband

Today, most North American Internet users have broadband access, from home or work, though broadband is more accessible in many European and Asian countries than in North America (Free speech and witch hunts 2005; Internet usage statistics 2006). Comparisons can be complicated by the fact that technologies with the same name sometimes have different performance characteristics: ADSL (asymmetric digital subscriber line) in Korea, for example, delivers 20 Mbps, while in Japan the rate is 26 Mbps, and in Switzerland it can be as low as 500 to 700 Kbps (Broadband 2004).

One of the implications for WBT of the increasing ubiquity of broadband is the increasing availability and lower cost of the accompanying technologies, including broadband-based TV (IPTV), and voice over Internet protocol (VoIP; voice only, or voice plus video). IPTV competes with satellite and cable versions in functionality, at considerably lower cost (Telcom broadcasting 2005).

Voice over Internet Protocol

VoIP permits the use of computers for voice and limited video communications, either as two-way private conversations or in multipoint group (class) sessions. While broadband is helpful, voice-only users may require no more than dial-up access to the Web, plus a sound card, microphone, and speakers. For voice and video, VoIP typically provides a small video display, with a refresh rate governed by bandwidth. (IP video is currently not of full-motion quality; its jerkiness and grainy nature lead some users to switch it off completely, relying on audio alone.) The quality of IP audio is usually good to very good. VoIP services are cheap, and may even be free for small numbers of users. Technical advancements, the low cost of VoIP, and growing experience suggest that this technology has a bright future in WBT situations, offering immediate advantages for interaction and support (Miller 2004; Dvorak 2005, The coming death of cheap VoIP, 2005, Inside track).

Wireless Systems

The cost of installing short-range "fixed" wireless systems in buildings or campuses is less than the cost of wiring

(or rewiring). Besides cost savings, wireless technologies install more quickly and are highly portable. Wi-Fi for small areas, and Wi-Max for areas up to 30 miles from the broadcast point, with transfer speeds of up to 15 Mbps, are available (Roush 2004; Hutson 2005; Fast tracked 2005; Why wait? 2005; Quain 2005). Wi-Max also offers a mobile capability, permitting reliable digital mobile TV transmission to handheld devices and PCs (Ellison 2005). The costs of other types of wireless technologies with wider coverage areas, such as cell phones and IM (instant messaging), are also dropping, and their reliability is increasing (Grimes 2003; Garfinkel 2004; Rupley 2004). All of these technologies have potential impacts on WBT, and some have already been tried successfully (www.wirelessdevnet.com).

Satellites provide a powerful, though more costly, alternative to ground-based data transmission for wide-spread, large-scale WBT systems. All the usual production costs apply to satellite-based delivery; costs may in fact be higher, since the greater potential audience warrants higher production values. In addition to the costs of developing and launching the satellite, the impact of equipment failure is significant, given the inconvenience of service calls.

Despite a downward trend in cost, wireless systems for WBT have some major disadvantages: even when transmission speeds are not slower than wired broadband (they often are), interference may lead to transmission errors, reducing effective speed (a problem exacerbated by the presence of other electronics); range depends on the site layout and configuration of the network (including building characteristics and materials); and wireless systems are more vulnerable to security threats.

Unproductive Internet Use and Addictive Behavior

Technology in general does not automatically increase productivity; in fact, there is evidence that it may even *decrease* productivity, especially in the short-term, while systems and people adjust to its presence (Fahy 1998; Dalal 2001). More serious problems arise from users' behavior, especially unauthorized use of technologies during work hours, and addiction. Both have implications for the productivity of WBT, especially where trainees are at a distance or are otherwise minimally supervised.

Huge amounts of time can be wasted online. In 2003, a study found that employees spent an average of 4.5 hours per week on the Internet at work for "personal reasons," leading 57 percent of employers to adopt policies defining legitimate Internet use (up from 33 percent in 2000) (Employees spend 2003). A more recent study found that half of employees surveyed spent from 1 to 5 hours online *daily* for personal reasons, most commonly reading the news, but also on travel, personal e-mail, shopping, and financial tasks (Punching out 2004). The problem is not new: some time ago, the U.S. Treasury Department noted that 40 percent of the inquiries it received came from workplaces, and e-Bay is one of the most often accessed Web sites from workplace locations. The problem is exacerbated by the fact that employees often do not perceive a problem with this use of their time and company resources: only one in ten employees in one survey felt using the Web for non-work reasons was unethical (Workers find 2001).

In addition to the potential for lost time (and drain on network resources) constituted by time spent online but off-task, some Web users become addicted to the technologies. For example, though only about one in four business e-mails actually requires immediate attention, one study found that substantial numbers of employees (34 percent) check their e-mail continually during the day, 42 percent check their business e-mail while on vacation, and 23 percent check it on weekends (E-mail addiction 2001), behavior that, if indicative of compulsive or addictive tendencies, requires WBT instructors' vigilance (Whittaker 2005; Breeding evil? 2005).

The above reinforces the point made previously that management of WBT requires attention to structure (to minimize intrusion of distractions) and dialogue (to discuss use of training time) (Moore 1991).

The Evolution of Media

Training media are changing as bandwidth improves, and as they do new technologies are presenting WBT designers with options and capabilities that were previously unavailable or uneconomical. Examples include the previously mentioned VoIP, and new portable presentation technologies, updated from the Web but used offline, and possessing high portability and vast storage capabilities.

Improvements in Storage and Portability of Information

For cheap, high-capacity storage, the CD has been replaced by the DVD. Blue-laser technology, though currently without a common standard, promises vastly greater storage (23 to 27 GB of storage currently demonstrated, with 50 GB promised), for both video and audio (Labriola 2004; Dvorak 2005, HD DVD).

Storage devices have also gotten much smaller, and capacities have soared: a terabyte (1000 GB, 35 to 100 hours of high-definition video) will soon reside on a device the size of a CD (Quain 2005, A new dimension). Conventional hard disks have also become smaller, while increasing in capacity (Miller 2004, Consumer electronics). Parallel developments in compression algorithms allow faster downloads and copying of popular formats such as MP-3 and MP-4, raising the effective storage capacities of existing devices (Murphy 2005; Make your own music 2004; MPEG-4 2005).

Practically speaking, there are few limitations to the capability of technology to store and deliver audio and, increasingly, video in highly portable forms for WBT. By downloading, users can take these materials with them, and use them when convenient, in an expanding variety of smaller and more portable hardware such as iPods, smart phones, and PDAs of various kinds.

M-learning developers see the implications of these technologies for video, but there are also impacts on stalwarts such as text and audio. E-books using e-paper can store up to 500 book-length documents on a portable device (Advanced materials 2005). Downloads are wireless. Portable devices also support podcasting, allowing anyone to produce and disseminate an audio only, or audio-plus-video, product, using only a PC, some

(usually free) special software, and a microphone (with videocamera, if desired). With RSS (variously, real simple syndication, or rich site summary) software, Podcasts can be sent ("pushed") automatically to subscribers (Magid 2005, DIY, 2005, RSS). These technologies are outgrowths of the phenomenally popular blog (Web log), a method of making one's formerly personal thoughts and experiences available to others, relatively effortlessly. The ease with which these can be produced is even more incentive for good instructional design: poor designs will be all too common, as anyone potentially becomes a producer.

Standards, and Reusable Learning Objects (RLOs)

Training materials are increasingly designed to be reused ("repurposed"), through standards developed by organizations such as the Aviation Industry CBT Committee (AICC), the Instructional Management Systems (IMS) Global Learning Consortium, the Institute of Electrical and Electronics Engineers (IEEE), and the Advanced Distributed Learning (ADL) Initiative of the Department of Defense (developer of SCORM [the Shareable Courseware Object Reference Model]) (SCORM best practices guide 2005). WBT instructional materials developed under RLO standards are portable, for maximum present and future (re)use. Metadata tagging of RLOs attempts to ensure several outcomes relevant to potential WBT uses (Longmire 2000):

- Flexibility—material is designed for multiple contexts and easy adaptation for reuse.
- Ease of update, search, and content management—metadata tags provide sophisticated filtering and selecting capabilities.
- Customization—modular learning objects enable more rapid program development or revision.
- Interoperability—RLOs operate on a wide range of training hardware and operating systems.
- Competency-based training—competency-based approaches are promoted by RLOs; materials are tagged to competencies, rather than subjects, disciplines, or grade levels.

Evolution of the Internet: "New" Internets

Worldwide growth in commercial use of the public Web has resulted in ongoing efforts to replace it with a version reserved for research and academic use. In North America, Internet developments include Canada's CA*net 4, and the United States' Internet2.

CA*net 4 uses optical wavelengths to transmit data at a theoretical maximum shared rate of 40 Gbps. Termed the first such network in the world, by 2007 CA*net 4 will permit users "to establish and manage their own optical networks within a subset of the whole network" (RISQ 2005). Internet2 is a collaboration of 240 U.S. research and academic partners, including industry representatives, government (through the National Science Foundation), and international agencies (including Canada, through CA*net 2), to create an environment that "is not clogged with music, commercial entities and porn" (Rupley 2002). As with Canada's CA*net series of systems, research and education are the focus (Networking 2002). Both of these

new Internets are capable of handling "torrents of data," without "the proliferation of closed architectures, the tendency for companies to protect their interests rather than invest in standards-based solutions, increased security and safety concerns across a wide range of sectors, and ongoing scalability challenges," weaknesses that plague the existing Internet (Talbot 2005).

Although these new versions of the Internet are not yet available for general WBT, they show what a renewed and more regulated Internet might be capable of providing to users, for purposes such as training and education. With the speed, security, applications, and overall stability these new systems promise, WBT would become even more attractive and sustainable (Next Internet 2005).

CONCLUSION

All indicators suggest that WBT will continue to expand, grow, and become central to more forms of future training worldwide. That prediction is safe, both because so much has already been invested in the Internet delivery infrastructure and because the Web has already proven to be so effective in reducing direct training costs, increasing access, and addressing serious skills deficiencies in an increasingly competitive and technological world (Kaven 2005). Satellite and cable TV took 35 years to be adopted by 50 percent of North Americans, VHS took 10 years, the Internet 9 years, and DVD 6 years; broadband will likely take still less (Lawrence 2005). The average global citizen appears to have little fear of new technologies; trainers, therefore, can be confident of this tool's continuing role and usefulness into the future.

But the evolution of the Web is required to ensure the future of WBT: computers are still too complex, those who support them admit, and their availability is still not sufficiently equably distributed (Behind the digital divide 2005; Pontin 2005). It may even turn out that the computer is the wrong device for some parts of the world to access information and interaction: by price, and direct impact on the gross domestic product, the London Business School argues that cell phones should be distributed to the world's 4 billion poorest people (Calling an end 2005). The infrastructure for that technology may already be in place: 80 percent of the world's population lives within range of a cell-phone network, but only 25 percent have a cell phone (Less is more 2005).

Simple availability or use of a technology are not necessarily the best measures of utility or impact, as the above descriptions of misuse of computer-based applications should make clear. Experience with traditional forms of training delivery have demonstrated that instructional design and conscientious monitoring, perhaps even more than the medium, makes training effective, and trainee support and overall relevance of the content make it appealing to users—lessons that have been available to WBT for some time (Dede 1991).

Although WBT cannot guarantee that future training will not be pedestrian or inefficient, its potential strengths may suggest how training of all kinds might be improved. The core elements of the Web as a training tool—ubiquity, accessibility, stability, redundancy, economy, and user-friendliness—are common to other successful teaching

environments. For WBT to expand, developers, managers, trainers and trainees, and employers must see these aspects of the Web as potential assets for their training programs. If the inherent features of the Web are seen as important to training, continued growth and expansion of WBT will occur.

GLOSSARY

Asynchronous: “Different time” (and often different place, i.e., the trainees’ workplace or home) training and interpersonal interactions, made possible by technologies that collect messages and make them available at the convenience of the reader. Examples include e-mail, CMC, and listservs.

Bandwidth: The capacity of a channel (e.g., a telephone line or a coaxial cable) to carry data. High bandwidth permits multimedia (audio, video, animation), while low bandwidth limits users to text or simple graphics, and may preclude VoIP and other new interactive tools.

Computer-Mediated Communications (CMC): Text-based, asynchronous communications, usually restricted by password to a designated group such as a class or training cohort, and moderated to ensure that the discussion stays on topic and is civil.

Content Management System (CMS): Software that permits the arrangement and presentation of training content through various fixed and m-learning devices.

Internet: The public network of linked computers accessible by anyone with a Web browser.

Intranet: A private computer network that may or may not also provide Web access, providing security and control not available on the public Internet by limiting access and controlling the content available to users.

Learning Management System (LMS): A tool for delivering, tracking, and reporting on the progress of trainees using m-learning systems, often in connection with a CMS.

Malware: Any form of malicious code intended to infect a computer or a network, including viruses, worms, and Trojan horse programs.

Markup Languages: Used for placing content on the Web; examples include HTML, XML, and SGML.

Metadata: The identifying material added to reusable learning objects (RLOs) to permit easy reuse or “repurposing.”

Mobile Learning (M-Learning): Use of various portable communications devices to access information and training content.

Online: Training that provides synchronous or asynchronous (often Internet-based) interaction between the trainee and the trainer, the training content, and other trainees.

Pervasive Computing: Embedding information into the entire environment of an organization, through use of portable (including wearable) and desktop devices of all kinds.

(Reusable) Learning objects (RLOs): Materials modularized, packaged, and labeled (tagged) to encourage cataloguing, access, and reuse in multiple contexts.

Synchronous: Same time and (often) same place training or communication interactions—for example, face-to-face training.

Training: Instruction in procedural skills and knowledge primarily for practical purposes and relatively immediate application.

Voice (or Video) over Internet Protocol (VoIP): The capability of Internet-based programs to provide voice point-to-point or point-to-multipoint connections to anyone with a browser, a sound card, a microphone, and speakers; may also include limited video or graphics capabilities.

The Web: A synonym for the Internet (in the context of this paper).

Web-Based Training (WBT): Includes training-on-the-job (TOJ) and workplace training, formal on-campus technical training, and elements of training or professional development (PD), including some online components, with the Internet or an intranet as the access/delivery vehicle.

INTRODUCTION

Radio-frequency identification (RFID) is a rapidly growing technology that has the potential to make great economic impacts on many industries. Although RFID is a relatively old technology, more recent advances in chip manufacturing technology are making RFID practical for new applications and settings, particularly tagging at the consumer-item level. These advances have the potential to revolutionize supply-chain management, inventory control, and logistics.

At its most basic, RFID systems consist of small transponders, or tags, attached to physical objects. RFID tags may soon become the most pervasive microchip in history. When wirelessly interrogated by RFID transceivers, or readers, tags respond with some identifying information that may be associated with arbitrary data records. Thus, RFID systems are one type of automatic identification system, similar to optical bar codes. There are many kinds of RFID systems used in different applications and settings. These systems have different power sources, operating frequencies, and functionalities. The properties and regulatory restrictions of a particular RFID system will determine its manufacturing costs, physical specifications, and performance. Some of the most familiar RFID applications are item-level tagging with electronic product codes, proximity cards for physical access control, and contact-less payment systems. Many more applications will become economical in the coming years.

RFID adoption yields many efficiency benefits, but it still faces several hurdles. Besides the typical implementation challenges faced in any information technology system and economic barriers, there are major concerns over security and privacy in RFID systems. Without proper protection, RFID systems could create new threats to both corporate security and personal privacy.

In this section, we present a brief history of RFID and automatic identification systems. I summarize several major applications of RFID. I also present a primer on basic RFID principles and discuss the taxonomy of various RFID systems. Then I address the technical, economic, security, and privacy challenges facing RFID adoption.

Finally, I briefly discuss emerging technologies relevant to RFID.

RFID Origins

The origins of RFID technology lie in the nineteenth century, when luminaries of that era made great scientific advances in electromagnetism. Of particular relevance to RFID are Michael Faraday's discovery of electronic inductance, James Clerk Maxwell's formulation of equations describing electromagnetism, and Heinrich Rudolf Hertz's experiments validating Faraday and Maxwell's predictions. Their discoveries laid the foundation for modern radio communications.

Precursors to automatic radio-frequency identification systems were automatic object-detection systems. One of the earliest patents for such a system was a radio transmitter for object detection designed by John Logie Baird in 1926 (Baird 1928; Auto-ID Labs 2006). More well known is Robert Watson-Watt's 1935 patent for a "Radio Detection and Ranging" system, or RADAR. The passive communication technology often used in RFID was first presented in Henry Stockman's seminal paper "Communication by Means of Reflected Power" in 1948.

One of the first applications of a radio-frequency identification system was in "Identify Friend or Foe" (IFF) systems deployed by the British Royal Air Force during World War II (Royal Air Force 2006). IFF allowed radar operators and pilots to automatically distinguish friendly aircraft from enemies via RF signals. IFF systems helped prevent "friendly fire" incidents and aided in intercepting enemy aircraft. Advanced IFF systems are used today in aircraft and munitions, although much of the technology remains classified.

Electronic detection, as opposed to identification, has a long history of commercial use. By the mid- to late 1960s, electronic article surveillance (EAS) systems were commercially offered by several companies, including Checkpoint Systems and Sensormatic. These EAS systems typically consisted of a magnetic device embedded in a commercial product and would be deactivated or removed when an item was purchased. The presence of an activated tag passing through an entry portal would

trigger an alarm. These types of systems are often used in libraries, music stores, and clothing stores. Unlike RFID, these types of EAS systems do not automatically identify a particular tag; they just detect its presence.

Auto-Identification and RFID

In terms of commercial applications, RFID systems may be considered an instance of a broader class of automatic identification (auto-ID) systems. Auto-ID systems essentially attach a name or identifier to a physical object by some means that may be automatically read. This identifier may be represented optically, electromagnetically, or even chemically.

Perhaps the most successful and well-known auto-ID system is the universal product code (UPC). The UPC is a one-dimensional, optical barcode encoding product and brand information. UPC labels can be found on most consumer products in the United States. Similar systems are deployed worldwide.

The Uniform Code Council (UCC), a standards body originally formed by members of the grocery manufacturing and food distribution industries, originally specified the UPC (Uniform Code Council 2006). A precursor body to the UCC first met in 1969 to discuss the need for an interindustry auto-ID system. By 1973, a one-dimensional (or linear) barcode design was chosen. In 1974, a supermarket in Ohio scanned the first UPC-labeled product: a package of Wrigley's gum.

Adoption of the UPC grew steadily throughout the following years, to the point at which UPC barcode scanners are found in a vast majority of large American retailers. Today, over 5 billion barcodes are scanned around the world each day. Shipping and transit companies, such as United Parcel Service, Federal Express, and the U.S. Postal Service, commonly use two-dimensional barcodes, which can carry more data in a smaller surface area.

Optical barcodes offer faster, more reliable, and more convenient inventory control and consumer check-out than checking out by hand. Several weaknesses of optical barcodes are that they require line-of-sight and may be smudged or obscured by packaging. In most circumstances, optical barcodes still require some human manipulation to align a barcode label with a reader. Supermarket shoppers have certainly experienced a checker struggling to scan an optical barcode.

Auto-ID systems that transmit data via RF signals (i.e., RFID) do not have the same performance limitations as optical systems. Data may be read without line-of-sight and without human or mechanical intervention. A key advantage in RF-based auto-ID systems is parallelism. Modern RFID systems may offer read rates of hundreds of items per second.

APPLICATIONS

Early commercial examples of RFID applications include automatic tracking of train cars, shipping containers, and automobiles. Railroad cars were originally labeled with optical bar code labels for tracking. These labels began to deteriorate and be obscured by dirt, causing reads to fail.

As a solution, railroad companies began to tag railcars with RFID devices. By 1994, these devices were mandatory, and nearly every railcar in the United States was tagged.

RFID devices began to be used for automated toll collection in the late 1980s and early 1990s. Electronic toll systems have since been adopted around the world. Like railway and shipping applications, electronic toll systems may use sturdy, self-powered RFID devices. Automobiles, railcars, and shipping containers are all high-value items, with ample physical space that can accommodate more expensive and bulky RFID devices. These types of tags could offer much more functionality than simple identification. For example, shipping containers might have accelerometer sensors, tamper alarms, or satellite tracking integrated into an identification device.

As manufacturing costs dropped, RFID systems began to be used for lower-value items in industries other than transportation. An example is in animal identification of both pets and livestock. Glass-encapsulated RFID devices have been implanted in millions of pets throughout the United States. These tags allow lost animals to be identified and returned to their rightful owners. These tags have a very short read range. Livestock, particularly cattle, are often labeled with a RFID device that is clamped or pierced through their ear, attached to a collar, or swallowed. Unlike implanted pet tags, these RFID devices are rugged and able to be read from greater distances. Concerns over bovine spongiform encephalopathy (mad cow disease) have motivated proposals for universal tracking of livestock with these types of RFID systems. Like transport applications, animal tracking is still essentially a low-volume, high-value market that may justify relatively expensive RFID systems.

Other widespread applications of RFID systems include contact-less payment, access control, or stored-value systems. Since 1997, ExxonMobil gasoline stations have offered a system called Speedpass that allows customers to make purchases with an RFID fob, typically a keychain-sized form factor (ExxonMobil Speedpass 2006). In 2005, American Express launched a credit card enhanced with RFID that allows customers to make purchases without swiping a card (RFID Journal 2005).

RFID proximity cards or "prox cards" are commonly used for building access control at many companies and universities throughout the world. Similar systems have been used for ski-lift access control at ski resorts. Many subway and bus systems, for example in Singapore, use stored-value RFID proximity cards.

There are several applications that use RFID as an anticounterfeiting measure. In 2005, the Wynn Casino in Las Vegas first opened and deployed RFID-integrated gaming tables and gambling tokens. These "chips-in-chips" are designed to frustrate counterfeiting, prevent theft, detect fraud, and offer enhanced games or service. Besides stored-value tokens like casino chips or event tickets, there have also been proposals to tag currency (Juels and Pappas 2003). In 2005, a controversial proposal to attach tags carrying biometric identification data to U.S. passports began to be implemented.

These applications also exposed some shortcomings of RFID. For instance, some RFID technologies do

not operate well in proximity to liquids or metals. Each technology has its own strengths and weaknesses, including variations in cost, size, power requirements, and environmental limits. There is no “one size fits all” RFID technology. The term *RFID technology* actually describes an entire array of technologies, which are each applicable to different types of applications. The section on “Principles” offers a detailed discussion of these various technologies.

RFID continues to lower the costs of tracking high-value items; however, an untapped and lucrative market lies in tracking cheap, everyday consumer goods. Companies like Proctor & Gamble, Coca-Cola, and Wal-Mart have hundreds of billions of products and components in their supply chains. Tracking and managing the flow of goods through these supply chains is a complex and expensive enterprise.

RFID technology may streamline these supply-chain processes and save billions of dollars, savings that ultimately may be passed on to consumers. Shipping pallets or, ideally, individual items may be tracked and traced from manufacturers, through transport, wholesale, and retail into the hands of the consumer at a point of sale. Products could even be tracked postconsumer as they are recycled, refurbished, or disposed of. What happens with respect to privacy while RFID-tagged items are in the hands of a consumer has been an issue of major contention and will be addressed in the section on “Security and Privacy.”

Supply-chain management and inventory-control applications of this scale require an extremely low-cost tag to be economically viable. In settings like animal identification, proximity cards, electronic toll systems, or stored-value systems, RFID tags costing as much as several U.S. dollars could be justified. However, items in consumer supply-chain management and inventory-control applications are much cheaper than in traditional settings. Ideally, RFID tags in these applications should be as simple and cheap as the traditional UPC optical bar code.

EPCglobal, an RFID standards body, has developed specifications for low-cost electronic product code (EPC) tags as a replacement for the ubiquitous UPC (EPCglobal 2006). In the past, the lack of an open standard was a barrier to RFID adoption. The EPC standard, and to some extent, the ISO-18000 standard (International Organization for Standardization 2004) will make it easier for users to integrate their RFID systems.

The potential for EPC may be huge. Globally, over 5 billion barcode transactions are conducted daily (Uniform Code Council 2006). Even minuscule savings per transaction could translate into a huge aggregate cost savings. The market has already begun to adopt low-cost RFID on a large scale. A single RFID IC manufacturer, Philips Semiconductor, has already shipped several billion RFID chips.

Organizations with large supply chains are the driving force behind RFID adoption. In 2003, Wal-Mart, the world's largest retailer, mandated that all suppliers attach RFID tags to shipping pallets by the end of 2006 (RFID Journal 2003, Wal-Mart). The U.S. Department of Defense (2006) issued a similar mandate for its own suppliers.

An illustrative example of an industry adopting RFID by way of mandate is the prescription drug industry, which must contend with a counterfeit drug market predicted to grow to \$75 billion by 2010 (World Health Organization 2006). In response to the growing problem of counterfeit drugs, the Food and Drug Administration (FDA; 2004) recommended that all wholesale prescription drug shipments be labeled with RFID pedigrees. The goal of these pedigrees is to both attest to the authenticity of a drug shipment and detect simple theft in the supply chain.

Some consumer industries may be independently motivated to adopt RFID early. In 2003, razor manufacturer Gillette placed a single order of 500 million low-cost RFID tags from a manufacturer named Alien Technologies (RFID Journal 2003, Gillette). Gillette disposable razor blade cartridges are relatively expensive, costing \$1 to \$2 per blade or more.

Because these items are small and easily concealable and there is a constantly growing resale market, Gillette blades were one of the most frequently shoplifted consumer items. Somewhere between 15 and 20 percent of Gillette's blades are stolen (or “shrink”) between manufacturer and the consumer point of sale. The high costs of “shrinkage” justified incorporating RFID tags into every razor blade package that Gillette sells.

The fashion industry has also been an early RFID adopter. Several fashion makers like Swatch watches, Ecco shoes, Prada, and Benetton (which will be discussed more in the section on “Challenges”) have all tagged clothing with RFID labels. These tags are typically for retail inventory control, since retail clothing stores often face a high level of shrinkage, as well as a lot of legitimate movement of inventory by customers trying on clothing.

RFID tags have also been used as a pedigree for high-fashion items or to enhance the consumer shopping experience. For example, Prada's retail store in New York City offers an RFID-enhanced dressing room that displays product information and suggests matching apparel.

Clothing is particularly suited for RFID, since it does not contain metals or liquids that interfere with some types of RFID systems. Retail stores also typically do not have sensitive electronics, like medical equipment, that some RFID operating frequencies may interfere with. Clothing's relatively high per-unit value also justifies the use of RFID tags, which can be removed and recycled at purchase time. The clothing industry was an early adopter of simple EAS systems in the 1960s for these very reasons. It will likely be a leader in RFID adoption as well.

The next step in RFID for clothing may be to integrate tags directly in the product at the time of manufacture, rather than manually attaching temporary tags. This greatly lowers RFID handling costs. Directly incorporating RFID into products or packaging will likely become commonplace once the proper technology becomes economical. A promising direction is to print RFID labels directly into paper products during manufacturing. This would greatly lower the handling and processing costs of integrating RFID with consumer products. We discuss printed circuits more in the section on “Future Technologies.”

Before delving into a more detailed discussion of various RFID technologies and principles, we will summarize

several of the present and envisioned future applications of RFID:

- Tracking and identification:
 - Large assets—e.g., railway cars and shipping containers
 - Livestock with rugged tags
 - Pets with implanted tags
 - Supply-chain management with EPC
 - Inventory control with EPC
 - Retail checkout with EPC
 - Recycling and waste disposal
- Payment and stored-value systems:
 - Electronic toll systems
 - Contact-less credit cards—e.g., American Express Blue card
 - Stored-valued systems—e.g., ExxonMobil Speedpass
 - Subway and bus passes
 - Casino tokens and concert tickets
- Access control:
 - Building access with proximity cards
 - Ski-lift passes
 - Concert tickets
 - Automobile ignition systems
- Anticounterfeiting:
 - Casino tokens—e.g., Wynn Casino Las Vegas
 - High-denomination currency notes
 - Luxury goods—e.g., Prada products
 - Prescription drugs

PRINCIPLES

This section discusses basics of RFID systems and offers taxonomy for the many various types of RFID systems. We briefly discuss two major RFID standards and how they relate to practice.

System Essentials

Discussion of RFID technology tends to focus only on tag devices. It is more accurate to view RFID as a complete system that includes not only tags, but also other important components. RFID systems are composed of at least three core components:

- RFID tags, or transponders, carry object-identifying data.
- RFID readers, or transceivers, read and write tag data.
- Databases associate arbitrary records with tag identifying data.

We illustrate the interaction of these components in Figure 1. In this figure, three tags are readable by one or both of two readers, A and B. For instance, tag 1 is readable only by A, while 2 is readable by both A and B, perhaps because of access-control restrictions. The readers then may connect to databases with records associated with particular tag identifiers. In this case, two databases each have their own record for tag 1.

Figure 1: Illustration of RFID System Interaction

Tags

Tags are attached to all objects to be identified in an RFID system. A tag is typically composed of an antenna or coupling element and integrated circuitry. An important distinction that will be discussed later is a tag's power source. Often tags carry no on-board power source and must passively harvest all energy from an RF signal.

There are many types of tags that offer different functionalities, have different power sources, or operate at different radio frequencies. Each of these variables helps determine which applications a particular tag may be appropriate for and what the costs of a tag may be. These differences will be discussed further in the section on "Power Sources."

Modern tags tend to implement identification functionality on an integrated circuit (IC) that provides computation and storage. In the manufacturing process, this IC is attached or "strapped" to an antenna before being packaged in a form factor, like a glass capsule or foil inlay, that is integrated into a final product.

In practice, different vendors often perform each of these manufacturing steps. Other RFID designs may be "chipless" or have identifying information hardwired at fabrication time—that is, "write-once, read-many" tags. Newer technologies that allow RFID circuitry to be printed directly onto a product will be discussed in the section on "Emerging Technologies."

Readers

RFID readers communicate with tags through an RF channel to obtain identifying information. Depending on the type of tag, this communication may be a simple ping or may be a more complex multiround protocol. In environments with many tags, a reader may have to perform an anticollision protocol to ensure that communication conflicts do not occur. Anticollision protocols permit readers to rapidly communicate with many tags in serial order.

Readers often power what are called "passive tags" through their RF communication channel. These types of tags carry no on-board power and rely solely on a reader to operate. Since these tags are so limited, many subsequently rely on a reader to perform computation as well.

Readers come in many forms, operate on many different frequencies, and may offer a wide range of functionality. Readers may have their own processing power and internal storage, and may offer network connectivity. Readers might be a simple conduit to an external system, or could store all relevant data locally.

Currently, many applications rely on fixed reading devices. Early trials of EPC at a major supermarket chain integrated fixed readers into docking-bay entrances. These readers scan tags at the pallet level as shipments

of products arrive. In the long term, readers may be integrated at a shelf level as a “smart shelf.” Smart shelves would scan for tags at the item level and monitor when they are added and removed from a shelf.

RFID readers may also be integrated into handheld mobile devices. These mobile readers would allow someone to, for example, take inventory of a warehouse by walking through its aisles. The cellular phone manufacturer Nokia is already offering RFID-reading functionality in some of their cell phones (Nokia 2004). If EPC-type tags become highly successful, interesting and useful consumer applications might arise. If this occurs, RFID reading functionality might become a common feature on cellular phones, personal digital assistants (PDAs), or other handheld computing devices.

Databases

RFID databases associate tag-identifying data with arbitrary records. These records may contain product information, tracking logs, sales data, and expiration dates. Independent databases may be built throughout a supply chain by unrelated users, or they may be integrated in a centralized or federated database system.

Databases are assumed to have a secure connection to readers. Although there are scenarios in which readers may not be trusted, it is often useful to collapse the notions of reader and database into one entity. For example, if tags contain all relevant product information, there is no need to make a call to an off-site database.

One may imagine a federated system of back-end databases, perhaps in which each product manufacturer maintains its own product look-up service. In these settings, it may be useful to deploy an object naming service (ONS) to locate databases associated with some tag identification value. An ONS allows a reader to find a set of databases associated with a particular tag identification value. This is analogous to the Internet domain naming service (DNS) that returns addresses of name servers that can translate domain names to numerical IP addresses. ONS has not yet been adopted widely in practice.

Power Sources

As briefly mentioned above, tags may obtain their power in several different ways. The power source is an essential property of a tag, since it will determine a tag's potential read range, lifetime, cost, and kinds of functionalities it may offer. The power source will also be important in determining how a tag may be oriented and what physical forms it may take.

There are three main classes of tag power sources: active, semipassive, and passive. Active tags have their own source of power, such as a battery, and may initiate communication with a reader or other active tags. Because they contain their own power source, active tags typically have a much longer operating range than passive tags. Large-asset- and livestock-tracking applications often use active tags, since the items they are attached to (e.g. railcars, shipping containers, or cattle) are high in value and have physical space for a bulkier, rugged tag.

A key feature of active tags is that they are able to initiate their own communication with readers. Advanced

active tags, or “smart dust,” might even form ad hoc peer networks with each other. One useful application of active tags is in shipping containers, which can fall off ships over rough seas. These missing containers sometimes are not accounted for until well after the ship has docked. An active tag with an accelerometer sensor could detect when it was falling off a stack of containers and broadcast a log of its demise before it sank into the ocean. Active tags could also function as security alarms using the same functionality.

By contrast semipassive (or semiactive) tags have an internal battery, but are *not* able to initiate communications. This ensures that semipassive tags are active only when queried by a reader. Because semipassive tags do have an internal power source, they do offer a longer reader range than passive attacks, but at a higher cost.

An example application that often uses semipassive tags is electronic tollbooths. Semipassive tags are typically affixed to the inside of a car's windshield. When the car passes through a tollbooth, it will initiate a query to the semipassive tag and read an account identifier from the tag. The on-board battery lets the tag be read from a considerable distance. However, since the tag needs to broadcast only when queried, it can remain idle most of the time and save power. Semipassive tags are also often used in pallet-level tracking or for tracking components like automobile parts during manufacture.

Passive tags have neither their own power source nor the ability to initiate communication. Passive tags obtain energy by harvesting it from an incoming RF communication signal. At lower frequencies, this energy is typically harvested inductively, while at higher frequencies it is harvested through capacitance.

Passive tags have the shortest read range of all three powering types, and they are the cheapest to manufacture and the easiest to integrate into products. Batteries are relatively expensive and cannot easily be incorporated into some items, like paper packaging. For this reason, passive tags are the most common tags. EPC tags are passive. Lacking an internal power source dictates many properties of passive tags. First, they cannot operate without the presence of a reader, although passive tags could temporarily cache some energy in a capacitor. Because of their necessarily weak response signal, passive tags are often more sensitive to environmental noise or interference. Table 1 compares various properties of passive, semipassive, and active tags.

Operating Frequencies

Different RFID systems operate at a variety of radio frequencies. Each range of frequencies offers its own operating range, power requirements, and performance. Different ranges may be subject to different regulations or restrictions that limit what applications they can be used for.

The operating frequency determines which physical materials propagate RF signals. Metals and liquids typically present the biggest problem in practice. In particular, tags operating in the ultrahigh frequency (UHF) range do not function properly in close proximity to liquids or metal.

Table 1: Comparison of Passive, Semipassive, and Active Tags

Tag Type	Power Source	Communication	Max Range	Relative Cost	Example Applications
Passive	Harvesting RF energy	Response only	10 M	Least expensive	EPC Proximity cards
Semipassive	Battery	Response only	>100 M	More expensive	Electronic tolls Pallet tracking
Active	Battery	Respond or initiate	>100 M	Most expensive	Large-asset tracking Livestock tracking

Table 2: Common RFID Operating Frequencies

Frequency Range	Frequencies	Passive Read Distance
Low frequency (LF)	120–140 KHz	10–20 cm
High frequency (HF)	13.56 MHz	10–20 cm
Ultrahigh frequency (UHF)	868–928 MHz	3 m
Microwave	2.45 and 5.8 GHz	3 m
Ultrawide band (UWB)	3.1–10.6 GHz	10 m

Operating frequency is also important in determining the physical dimensions of an RFID tag. Different sizes and shapes of antennae will operate at different frequencies. The operating frequency also determines how tags physically interact with each other. For instance, stacking flat foil inlay tags on top of each other may cause interference and prevent tags from reading properly. Table 2 lists standard frequencies and their respective passive read distances.

Low Frequency

Low-frequency (LF) RFID tags typically operate in the 120-to-140-kHz range. Most commonly, LF tags are passively powered through induction. As a result, they typically have very short read ranges of 10 to 20 cm.

LF tags can be used in rugged environments and can operate in proximity to metal, liquids, or dirt. This makes them useful for applications like implantable pet identification tags or laundry-management tags. One disadvantage of LF tags is that they have a very low data read rate compared with other operating frequencies.

LF tags are often used in car-immobilization and access-control systems. In these systems, a car will start only if an LF tag, typically attached to the ignition key, is in proximity to the ignition. This takes advantage of LF's short read range and uses it as a security feature.

In 2006, LF passive tags may be purchased in bulk for \$1 per tag or less. Two major manufacturers of LF tags are Texas Instruments and Phillips Semiconductor. The ISO 18000-2 standard offers specifications for LF RFID tags (International Organization for Standardization 2004).

High Frequency

High-frequency (HF) RFID tags operate at the 13.56-MHz frequency. HF tags are often packaged in a foil inlay or credit card form factor. This makes HF tags useful for building access control, contact-less credit cards, and ID badges. Again, the relatively short read range of HF is an advantage in these settings.

HF tags are also used in many asset-tracking applications. Libraries and bookstores often use HF foil inlays to track books. Some airports have started using HF RFID luggage tags for baggage-handling applications.

HF tags offer a higher data read rate than LF tags, but do not perform as well as LF tags in proximity to metals or liquids. HF tags do, however, offer better performance near metals or liquids than UHF tags do.

The HF frequency range lies on a heavily regulated part of the radio spectrum. Signals broadcast by readers must operate in a narrow frequency band. This presents a problem for environments with sensitive electronics, like medical equipment, that operate on similar frequencies. This makes HF tags inappropriate for environments like hospitals. In 2006, HF passive tags may be purchased in quantity for \$0.50 or less per tag. Texas Instruments and Phillips both offer HF tag lines, although there are many smaller and specialized manufacturers or integrators in the HF space.

International Standards Organization (ISO) specifications for HF RFID tags are specified by the ISO 18000-3 standard (International Organization for Standardization 2004). Related specifications for HF contact-less smart cards and proximity cards appear in ISO standards 14443 and 15693 (International Organization for Standardization 2003).

Ultrahigh Frequency

Ultrahigh frequency (UHF) RFID tags operate in the 868-to-928-MHz range. European tags typically operate within the 868-to-870-MHz range, while the United States and Canada operate at 902 to 928 MHz.

UHF tags are most commonly used for item tracking and supply-chain-management applications. This is largely because they offer a longer read range and are cheaper to manufacture in bulk than LF or HF tags. The first-generation EPC tags operate at UHF.

A major disadvantage of UHF tags is that they experience interference in proximity to liquids or metals. Many applications like animal tracking, metal-container tracking, or even many access-control systems are not feasible with UHF tags. Some materials have been

developed that may shield UHF tags from metal-related distortion, but these may be cost-prohibitive to use in practice. UHF readers may also interfere with sensitive electronics like medical equipment.

UHF tags are a relatively newer technology than LF or HF, and reader costs are typically higher than the lower-bandwidth LF readers. In 2006, UHF tags can be purchased in quantities for under \$0.15 per passive tag. UHF tags costing as low \$0.05 are likely to come to the market in coming years. Specifications for RFID tags operating at UHF frequencies are defined by both the ISO 18000-6 International Organization for Standardization 2004) standard and the EPCglobal standard (EPCglobal 2006).

Microwave

Microwave tags operate at either 2.45 or 5.8 GHz. This frequency range is sometimes referred to as super high frequency (SHF). Microwave RFID technology has come into use fairly recently and is rapidly developing. Microwave tags used in practice are typically semipassive or active, but may also come in passive form. Semipassive microwave tags are often used in fleet identification and electronic toll applications.

Microwave systems offer higher read rates than UHF and equivalent passive read ranges. Semipassive and active read ranges of microwave systems are often greater than their UHF counterparts. Some microwave active tags may be read from ranges of up to 30 m, which is less than comparable UHF tags. However, physical implementations of microwave RFID tags may be much smaller and more compact than lower-frequency RFID tags.

There are several downsides to microwave tags. One is that they consume comparatively more energy than their lower-frequency counterparts. Microwave tags are typically more expensive than UHF tags. Commercially available active tags cost as much as \$25 per tag in 2006.

Another problem is that wireless 802.11b/g (WiFi) networks may interfere with microwave RFID systems. Devices implementing the upcoming ZigBee 802.15 wireless standard could also potentially conflict with microwave RFID devices as well. The ISO 18000-4 and the rejected ISO 18000-5 (International Organization for Standardization 2004) standards offer respective specifications for 2.45- and 5.8-GHz RFID tags.

Ultrawide Band

Ultrawide band (UWB) technology applied to RFID is fairly recent. Rather than sending a strong signal on

a particular frequency, UWB uses low-power signals on a very broad range of frequencies. The signal on a particular frequency used by UWB is very weak, but in aggregate, communication is quite robust. In practice, some implementations of UWB operate from 3.1 to 10.6 GHz.

The advantages of UWB are that it has a very long line-of-sight read range, perhaps 200 m in some settings. UWB is also compatible with metal or liquids. Since the signal on a particular frequency is very weak, UWB does not interfere with sensitive equipment. Consequently, an early application was asset tracking in a hospital setting.

A disadvantage of current implementations of UWB is that it must be active or at least semipassive. However, since UWB tags broadcast very weak signals, they have relatively low power consumption. As of 2006, it is unclear whether the technology exists to create a passive UWB tag. (Multifrequency passive tags operating at HF, UHF, and microwave do exist in 2006. Although they do not operate as UWB tags, supporting multifrequency communications is possible in a passive setting.)

UWB RFID technology is still in its early phases and there are few commercial products available. Costs of \$5 per tag in bulk are reasonable in the near future.

Functionality

The basic RFID functionality is identification. When queried by a reader, tags return some identifier that may be used to retrieve other data records. However, tags may offer various other functionalities useful in different applications. The underlying principles and technologies of these various types of tags are so closely related to strict RFID tags, that they often collectively referred to as "RFID." Although not strictly RFID, I discuss several major classes of RFID-related devices.

RFID-style tags are split into five broad classes: EAS, read-only EPC, EPC, sensor tags, and motes. These will be referred to as classes A through E. EPCglobal (2006) offers five similar classes of tag based on functionality dubbed class 0 through class 4. The EPCglobal classes closely align with ours, but differ somewhat. These five classes are summarized in Table 3.

Difficult technical and economic problems arise in class B and particularly class C devices. EAS tags are so limited in function that they are extremely simple and cheap to manufacture. By contrast, class D and E devices offer enough functionality to justify higher manufacturing

Table 3: Tag Functionality Classes

Class	Name	Memory	Power Source	Features
A	EAS	None	Passive	Article surveillance
B	Read-only EPC	Read-only	Passive	Identification only
C	EPC	Read/write	Passive	Data logging
D	Sensor tags	Read/write	Semipassive	Environmental sensors
E	Motes	Read/write	Active	Ad hoc networking

costs and can offer relatively ample resources. The challenge “sweet spot” lies in class B and class C devices, which are part of crucial systems, yet are still subject to tight resource and cost constraints.

Electronic Article Surveillance

Electronic article surveillance (EAS) tags are the most basic RFID-type tag and have been in commercial use for over 40 years. EAS tags do not contain unique identifying information, so technically are not RFID tags. They simply announce their presence to a reader. In other words, EAS tags broadcast a single bit of information—“Something is here.”

In practice, EAS tags are almost always passive and are often attached to compact discs, clothing items, or books in retail locations. EAS tags could be active or semipassive, but the added cost of a power source would greatly outweigh adding unique identifying functionality. Because of their limited functionality, EAS tags are the simplest and cheapest to manufacture.

Read-Only EPC

Unlike EAS tags, EPC tags contain some identifying information. EPCglobal refers to these tags as class B tags. This information may be a product code or a unique identifier. Read-only EPC tags have a single identifier that is written once when a tag is manufactured. Thus, class B tags offer strict RFID functionality. Class B tags will likely be passively powered. Although they could be semipassive or active, again the cost of a battery would greatly outweigh the cost of rewritable memory.

As the name suggests, EPC tags are used in basic item-tracking applications. However, many other practical applications of tags, such as smart cards or proximity cards, are using tags with read-only memory that offer simple identification. Read-only EPC tags are fairly simple and may even be “chipless,” and thus are relatively cheap.

Electronic Product Code

Class C refers to simple identification tags offering write-once, read-many or rewritable memory. Rather than having an identifier set at manufacture time, identifiers may be set by an end user. If an electronic product code (EPC) tag offers rewritable memory, its identifier may be changed many times. (Because of technical issues, “rewriteable” tags in practice typically can be written only some fixed number of times, perhaps several hundred.) Class C tags still offer strictly RFID functionality.

Class C EPC tags may be used as a logging device, or can emulate Class B read-only EPC tags. In practice, class B EPC tags may be passive, semipassive, or active. Strict RFID functionality includes class B tags. Supporting nonvolatile, writable memory adds complexity to class B tags. Consequently, they may be significantly more expensive than read-only EPC or EAS tags.

Sensor Tags

Sensor tags may contain on-board environmental sensors, and may log and store data without the aid of a reader. These types of tags will be referred to here as class D.

Sensor tags offer more than strict RFID functionality, and are typically not thought of as RFID.

Many sensor tags may form a “sensor net” that monitors a physical area’s environmental properties. This may include temperature changes, rapid acceleration, changes in orientation, vibrations, the presence of biological or chemical agents, light, sound, etc. Because they operate without a reader present, sensor tags must necessarily be semipassive or active. An on-board power source and sensor functionality comes at a much higher manufacturing cost.

Motes

Class E tags, or “smart dust” motes (Pister 2004), are able to initiate communication with peers or other devices, and form ad hoc networks. Motes are essentially general pervasive computing devices and are much more complex than simple EPC-style RFID. Because they are able to initiate their own communication, mote devices are necessarily active. Commercial motes are available from Crossbow Technology. Ongoing research into smart dust and motes is being conducted at the University of California, Berkeley, and at Intel.

Standards

The two most relevant RFID standards are the International Organization for Standardization’s ISO/IEC 18000 standard (International Organization for Standardization 2004) and EPCglobal’s standards (EPCglobal 2006). These standards are not competing, and it is conceivable that EPCglobal’s standard could eventually be adopted into an ISO standard.

EPCglobal defines specifications for EPC-type tags operating in the UHF range. The ISO 18000 standard has six parts addressing different frequency ranges:

- Part 1—General standards
- Part 2—LF
- Part 3—HF
- Part 4—Microwave, 2.45 GHz
- Part 5—Microwave, 5.8 GHz (withdrawn)
- Part 6—UHF

Two other ISO standards, ISO/IEC 14443 and ISO/IEC 15693 (International Organization for Standardization 2004), are related to smart card and proximity card interfaces operating in the HF range.

CHALLENGES

Technical

RFID systems still face many technical challenges and obstacles to practical adoption. A major hurdle is simply getting RFID systems to work in real-world environments. Systems that work perfectly in a lab setting may encounter problems when faced with environmental noise, interference, or human elements.

As an example, in 2005, a major retail chain tested RFID pallet-level tracking in their shipping and receiving cargo bays. The retailer experienced difficulties in achieving near 100 percent read rates and had unanticipated, mundane

technical issues. However, these issues will likely be ironed out as adoption becomes more commonplace.

Readers and tags have often experienced interference caused by other wireless systems or unknown sources. This type of interference was not systematic, and it usually resulted from environmental idiosyncrasies. Addressing these issues required trial and error and practical experience to recognize what was causing the problem. For example, simply repositioning or realigning readers would often address performance issues.

Software support for RFID is still in its early stages as well. Getting distributed back-end database look-ups to work in practice is a complex task that is often glossed over in the RFID literature. In particular, key management and network connectivity issues are often underemphasized. Many vendors do currently offer RFID software solutions. However, in the coming years it is likely that the industry will consolidate onto several standardized software interfaces.

The point of this digression is to emphasize that, like most information technology systems, RFID systems still require practical expertise to install, configure, and manage. End users should expect to experience mundane technical complications that arise while implementing RFID. Despite marketing claims to the contrary, RFID is not a “magic bullet” that is simple to implement out of the box.

Economic

A key hurdle that still remains in RFID systems is simply cost. This is especially the case with EPC item-level tagging. A commonly cited price point at which item-level tagging is supposed to be economically viable is \$0.05 per UHF tag.

As of 2006, the “5-cent tag” does not exist. Tag ICs alone (not including antennae or packaging), do cost as little as \$0.08, although these are being sold as a loss leader. It will likely be a number of years until tags are available at the 5-cent level, and then only in huge quantities. However, this may be an artificial breakpoint. Many applications could very well benefit from more expensive tags.

A second cost issue is readers, especially UHF readers, which retail in 2006 for well over \$1,000. At this price level, many firms may only afford a small number of readers in loading bays. “Smart shelves” that incorporate readers throughout a retail or warehouse environment would be prohibitively expensive for most applications.

As the market grows, RFID costs will drop and new applications will become economical, especially as more investment is made into back-end architectures. However, for the near future, the costs of many envisioned applications, particularly for EPC tags, are simply not justified.

Security and Privacy

Many concerns have been expressed over the security and privacy of RFID systems. Traditional applications, like large-asset tracking, were typically closed systems in which tags did not contain sensitive information. Tags on railway cars contained the same information painted

on the side of the cars themselves. However, as more consumer applications are developed, security, and especially privacy, will become important issues.

Much work has recently focused on issues of RFID security and privacy. Gildas Avoine (2006) maintains a comprehensive bibliography of RFID security and privacy papers. Ari Juels (2006) offers a survey of RFID security and privacy issues. These references provide a more comprehensive analysis.

Eavesdropping

Perhaps the biggest security concerns in RFID systems are espionage and privacy threats. As organizations adopt and integrate RFID into their supply chain and inventory-control infrastructure, more and more sensitive data will be entrusted to RFID tags. As these tags inevitably end up in consumers’ hands, they could leak sensitive data or be used for tracking individuals.

An attacker able to eavesdrop long range could possibly spy on a passive RFID system. Despite the fact that passive tags have a short operating range, the signal broadcast from the reader may be monitored from a long distance. This is because the reader signal actually carries the tag’s power, and thus necessarily must be strong.

A consequence is that a reader communicating with a passive tag in, for instance, a UHF setting might be monitored from a range up to 100 to 1000 m. Although this only reveals one side of a communication protocol, some older protocols actually broadcast sensitive tag data over the forward channel. Newer specifications, like EPCglobal class-1 generation-2, take care to avoid this.

Although short-range eavesdropping requires nearby physical access, it can still be a threat in many settings. For example, a corporate spy could carry a monitoring device while a retail store conducts its daily inventory. Alternatively, a spy could simply place bugging devices that log protocol transmissions.

Espionage need not be passive. Attackers could actively query tags for their contents. Rather than waiting to eavesdrop on legitimate readers, active attackers could simply conduct tag read operations on their own. Active attackers may be easy to detect in a closed retail or warehouse environment, but may be difficult to detect in the open.

Both eavesdropping and active queries pose threats to individual privacy. RFID tags can be embedded in clothes, shoes, books, key cards, prescription bottles, and a slew of other products. Many of these tags will be embedded without the consumer ever realizing they are there. Without proper protection, a stranger could tell what drugs you are carrying, what books you are reading, perhaps even what brand of underwear you prefer.

Many privacy advocates are extremely concerned about RFID (Albrecht and McIntyre 2005). In 2003, Benetton, a clothing maker, announced plans to label clothing with RFID and was promptly boycotted by several groups (Krane 2003). This illustrates the potential of consumer backlash over privacy to impede RFID adoption.

Besides leaking sensitive data, individuals might be physically tracked by the tags they carry. Of course, cellular phones can already track individuals. Unlike a cell phone, which is only supposed to be able to be tracked by a cellular provider, RFID tags might be tracked

by anyone (granted, within a relatively short read range). Readers will eventually be cheap to acquire and easy to conceal.

Clearly, tracking someone is trivial if an attacker is able to actively query unique identifying numbers from tags. Even if unique serial numbers are removed from tags, an individual might be tracked by the “constellation” of brands they carry. A unique fashion sense might let someone physically track you through an area by your set of favorite brands.

Many privacy countermeasures have been proposed that may efficiently mitigate many of these risks. We refer the reader to Juels’ survey (2006) and Avoine’s bibliography (2006) for more information.

Forgery

Rather than simply trying to glean data from legitimate tags, adversaries might try to imitate tags. This is a threat to RFID systems currently being used for access-control and payment systems. Although an adversary able to physically obtain a tag can almost always clone it, the real risk is someone being able to “skim” tags wirelessly for information that can be used to produce forgeries. For instance, if tags simply respond with a static identification number, skimming is trivial.

Forgery is obviously a major issue in RFID systems used specifically as an anticounterfeiting device. For example, the FDA (2004) proposed attaching RFID tags to prescription drug bottles as a pedigree. Someone able to produce forgeries could steal legitimate shipments and replace them with valid-looking decoys, or could simply sell counterfeit drugs with fake pedigree labels.

A cautionary example is the ExxonMobil Speedpass (2006), which uses an RFID keychain fob that allows customers to make purchase at ExxonMobil gas stations. A team of researchers from Johns Hopkins University and RSA Security broke the weak security in Speedpass and produced forgeries that could be used to make purchases at retail locations (Bono et al. 2005).

Fortunately, low-cost security countermeasures have been developed that allow readers to authenticate tags. For example, Juels and Weis (2005) offer a low-cost authentication protocol based on a hard learning problem that is efficient to implement in a tag. However, as of 2006, these protocols exist only on paper and are not available in any commercial products.

Denial of Service

Weaker attackers unable to conduct espionage or forgery attacks may still be able to sabotage RFID systems or conduct denial-of-service attacks. An adversary may simply jam communication channels and prevent readers from identifying tags. An attacker could also seed a physical space with “chaff” tags intended to confuse legitimate readers or poison databases. Locating and removing chaff tags might be very difficult in a warehouse environment, for instance.

Powerful electromagnetic signals could physically damage or destroy RF systems in a destructive denial-of-service attack. Fortunately, attempting these attacks from long range would require so much power that it would affect other electronic components and be easily detected.

Although these denial-of-service and sabotage attacks may seem to be simply nuisances, they could represent serious risks. This is especially true in defense or medical applications. For example, the U.S. Department of Defense is moving toward RFID-based logistics control. An attack against the RFID infrastructure could delay crucial shipments of war materiel or slow down troop deployments.

Viruses

In 2006, researchers demonstrated an RFID virus based on an system query language (SQL) injection attack (Rieback, Crispo, and Tanenbaum 2006). The virus payload was an SQL database query that would overwrite existing RFID identifiers in the database with the virus payload. When tags were updated from the infected database, the virus would be propagated.

This virus assumes that RFID contents are essentially “executed” without any validation. It also assumes that future reads from an infected system can overwrite tag contents, which is often not the case in practice. In fact, nothing about the virus was particular to RFID systems. Input from any source, whether a network connection, USB port, or keyboard, could spread viruses when insecurely executed without validation.

CONCLUSION AND FUTURE TECHNOLOGIES

Two promising technological developments especially relevant to RFID are printed circuits and organic components (Subramanian et al. 2006; University of California, Berkeley Organic Electronics Group 2006). These technologies have the potential to greatly lower manufacturing costs and to produce RFID tags built out of flexible plastic materials instead of silicon.

The long-term vision is that a large-scale packaging manufacturer could print RFID tags directly into paper or plastic as it is produced. Product makers would not use this RFID-enhanced packaging material as they normally would. One advantage in terms of privacy is that RFID tags would be attached only to product packaging, and not to the product itself.

This technology is still years away from being economical, and there are many hurdles to overcome. Currently, circuits printed by an inkjet printer have a very low resolution; circuit gates take much more surface area than traditionally fabricated circuits. Other technologies like gravure printing also produce relatively large circuit surface areas.

Regardless, much research is being focused on organic components for other purposes, like flexible displays. Developments in this area will benefit RFID, potentially opening the door to many inexpensive and interesting future applications.

GLOSSARY

Active Tag: A tag with its own battery that can initiate communications.

Auto-ID: Automatic identification. Auto-ID systems automatically identify physical objects through the use of optical, electromagnetic, or chemical means.

EAS: Electronic article surveillance. An RF device that announces its presence but contains no unique identifying data. EAS tags are frequently attached to books or compact discs.

EPC: Electronic product code. A low-cost RFID tag designed for consumer products as a replacement for the UPC.

HF: High frequency. ≥ 13.56 MHz.

IFF: Identify friend or foe. Advanced RFID systems used to automatically identify military aircraft.

LF: Low frequency. 120–140 KHz.

Linear Barcode: A one-dimensional, optical bar code used for auto-ID.

Passive Tag: A tag with no on-board power source that harvests its energy from a reader-provided RF signal.

Reader: An RFID transceiver, providing read and possibly write access to RFID tags.

RF: Radio frequency.

RFID: Radio-frequency identification. Describes a broad spectrum of devices and technologies, and is used to refer both to individual tags and overall systems.

Semipassive Tag: A tag with an on-board power source that is unable to initiate communications with a reader.

Skimming: An attack in which an adversary wirelessly reads data from a RFID tag, enabling forgery or cloning.

Tag: An RFID transponder, typically consisting of an RF coupling element and a microchip that carries identifying data. Tag functionality may range from simple identification to being able to form ad hoc networks.

UCC: Uniform Code Council. A standards committee originally formed by grocery manufacturers and food distributors that designed the UPC barcode.

UHF: Ultrahigh frequency. 868–928 MHz.

UPC: Universal product code. A one-dimensional, optical barcode found on many consumer products.

UWB: Ultrawide band. A weak communication signal is broadcast over a very wide band of frequencies—e.g., 3.1–10.6 GHz.

INTRODUCTION

The goal of active networking is to create communication networks that reposition static, low-level network operation into dynamic, differentiated, and adaptable behavior; often implemented by transferring low-level network operating code within the same packets that carry network traffic. This allows communication hardware to be more fully used given that its operation can be tailored to specific application requirements. This also enables a more flexible and survivable communication network. Active networking decouples the network protocol from its transport by allowing easy insertion of protocols on top of the transport layer. Active networking also minimizes requirements for global agreement; it does not require years of standards negotiation to introduce new protocols. Active networking enables on-the-fly experimentation given easy insertion of new protocols and network applications, thus enabling the rapid deployment of new services and applications. The mechanism for implementing an active network is to enable communication packets to carry network code as well as data. This code may be installed on the fly into low-level network devices as the packet flows through the network.

If one compares and contrasts the current Internet protocols and active and programmable networking shown in Figure 1, it should be noted that Internet protocols

have become fossilized, in other words resistant to radical change, whereas an active network is built for change. The Internet protocols are becoming burdened with layer upon layer of complexity; for example, there are on the order of 4000 RFCs (Requests for Comment) describing Internet protocols and operation. In contrast, a goal of active networking is to reduce complexity by allowing a common framework for protocol insertion. The Internet protocol has an inability to customize quickly or efficiently because of a long standardization process, whereas the active network concept is to provide a framework for rapid and efficient customization. The Internet protocols are well known for their lack of common or operable security paradigms. In contrast, the Security Framework for Active Networks has received considerable attention in order to provide a secure framework from the start. Finally, the Internet protocols appear to be on a downward slope in terms of innovation; in other words, new standards tend to add smaller and smaller evolutionary changes. In contrast, active networking allows significant room for an upward trend in innovation.

Active networking paradigms are being used in wireless and ad hoc communications. A trend is the exploration of self-organization and emergent behavior among autonomous packets. The latest research in this area can be found in conferences listed in the Further Reading section at the end of this chapter and in a journal issue focused on active networks (Bush and Kalyanaraman 2006).

The active network model provides user-driven customization of the network infrastructure, allowing new services to be deployed at a faster pace than can be sustained by vendor-driven consensus or through standardization. The essential feature of active networks is the programmability of its infrastructure. New capabilities and services can be added to the networking infrastructure on demand. This creates a versatile network that can easily adapt to future application needs. The ability to program new services into the network will lead to a

Figure 1: The contrast between current networks and active networks (RFC = Request for Comment)

user-driven innovation process in which the availability of new services will be dependent on their acceptance in the marketplace. In short, active networking enables the rapid deployment of novel and innovative services and protocols into the network. For example, a videoconferencing application can inject a custom packet-filtering algorithm into the network that, in times of congestion, filters video packets and allows only audio packets to reach the receivers. Under severe congestion, the algorithm compresses audio packets to reduce network load and alleviate congestion. This enables the application to handle performance degradation due to network problems gracefully and in an application-specific manner.

In an active network, applications not only determine the protocol functions as necessary at the end points of communication, but also inject new protocols into the network. The concept of active networking evolved from discussions within the Department of Defense's Defense Advanced Research Projects Agency (DARPA) community regarding future directions in communication networks. The purpose of these discussions was to design networks that overcome problems and limitations of existing networks. Some of the problems identified were:

- Existing networks cannot support rapid development and deployment of new protocols and services. Designing a new protocol requires acceptance from a standardization committee and later implementation and support from vendors before applications can use the protocol. Experience has shown that this is usually a long and tedious process. For example, work on the design of the Internet Protocol version 6 (IPv6) was initially started in 1995 but the protocol has still not found widespread deployment.
- The existing Internet model allows limited security in the form of secure sockets, application data encryption and firewalls, but it is still difficult to create seamless, secure virtual private networks over the Internet.
- Network functionality is scattered across routers, switches, end systems, link-level hardware and applications, which prevents gathering of coherent state and makes network management extremely difficult.
- Mobile devices have to be treated as static devices because it is not currently possible to move a mobile state seamlessly across the network.
- It is not possible to deploy new services such as adaptive transcoding or in-network data-fusion, when and where you want them dynamically. In current networks, services are rigidly built into kernels of operating systems of end systems and network devices, preventing on-the-fly customization of these services by the applications

To overcome the above limitations, DARPA began working on a set of ideas collectively referred to as active networking. The principal tenet of active networking is to devise the network architecture so that new features and services can be programmed into the network. The idea of carrying computation into the network is a natural evolution from circuit switching and packet switching, in terms of increasingly greater computational role in the network, as shown in Figure 2.

Figure 2: Active networks appear as a natural evolution of legacy networking

Research into active networking has provided the incentive to revisit what has traditionally been classified as distinct properties and characteristics of information transfer, such as protocol versus service; at a more fundamental level, this chapter considers the blending of computation and communication by means of descriptive complexity, discussed later. The specific active service examined in this chapter is network self-prediction enabled by an active application. Computation/communication is analyzed via Kolmogorov complexity. The result is a mechanism to understand and improve the performance of active networking.

Custom code is injected into the network in one of two ways, as shown in Figure 3. One approach is to download code to active nodes separately from data packets. The downloaded code carries computation required for some or all of the data packets flowing through the node. The code is invoked when the intended data packets reach the node. This is known as the discrete approach. The

Figure 3: Integrated (upper portion of figure) versus discrete (lower portion of figure) active packets (P = program) (D = data)

other approach is the capsule or integrated approach. In this approach, packets carry both computation as well as data. As packets flow through intermediate network nodes, the custom code is installed at some or all the nodes in the network. These packets are called “capsules” or “SmartPackets.” These are the basic unit of communication in an active network. Applications inject SmartPackets in the network and active nodes process the code inside the SmartPackets.

BACKGROUND

There is a general consensus that network architectures must be made programmable to enable application-specific customization of network resources and the rapid introduction of new services into the network. As a result, there are two schools of thought on the approach to be taken to make networks programmable. One effort is spearheaded by the OpenSig community, which argues that networks can be designed using a set of open programmable interfaces, opening access to network devices such as switches, routers, and hubs and thereby enabling third-party developers to devise custom solutions for their applications. The other approach is that of active networks, in which packets can contain custom code that executes in the execution environment provided by the nodes of the network. Thus, an active network is no longer node-centric but packet-centric; that is, the code in the active packets is executed at the intermediate network devices as the packet travels through the network. The result is that customized processing is accomplished as the packet is transmitted through the network. This enables experimentation and the rapid deployment of new services.

After the concept of active networking was initially conceived, researchers at the Massachusetts Institute of Technology developed a small proof-of-concept prototype using a Tcl (originally from “tool command language,” but nonetheless conventionally rendered as “Tcl” rather than “TCL,” and pronounced “tickle,” a *scripting language*) shell to demonstrate the potential of the new idea. This sparked interest among researchers initially in the United States (primarily because of the DARPA effort) and later worldwide. This can be evidenced from the chapters submitted to the March 2000 issue of the *IEEE Communications Magazine* and the participation in the International Conference on Active Networks (IWAN). There were a considerable number of research efforts that attempted to develop complex and varied execution platforms to study different facets of the model. This led to a plethora of custom execution platforms on small-scale active networks. However, the prototypes were limited to testbeds in individual research laboratories, which did not bode well for the deployment of active networks on a global scale. Therefore, in 1998, researchers across the active networking community challenged themselves to develop plans to deploy active networks on a large scale. The principal hurdle toward this goal was the total lack of interoperability between the execution platforms. The community decided that while the richness in diversity is desirable, it was necessary to develop a scheme that enabled diverse active network prototypes to communicate with each other.

The solution was to define a skeleton framework for an active node that divided its functionality into layers and to define the scope and properties of each layer. This enabled researchers to collaborate in the design of an active network in which active nodes can host several different execution platforms and yet can be connected to each other to provide an active network backbone. The framework is defined in a working document called the “Architectural Framework for Active Networks” (Calvert 1998).

Active networking provides a programmable infrastructure using a well-defined structure for packets that contain general-purpose program code and a uniform standardized execution platform on the nodes of the network. The next sections give the reader an overview of the basic model of an active network. They describe basic components and introduce common terminology.

ACTIVE NETWORK FRAMEWORK

There had been a few pioneering efforts that predate the term *active networks*; most notably, SOFTNET was used as an active ad hoc network in the early 1980s from the Radio Communication Systems Lab, Royal Institute of Technology, Stockholm, Sweden, which allowed dynamic network programming within packets; however, rapid acceleration in the development of active networks did not occur until the mid-1990s, with the funding by DARPA. Some early examples of active network applications included active routers that provide soft-state storage and “best-effort” caching so that lost packets can be retransmitted by the nearest upstream router and nacks (negative acknowledgments) are fused on the way to the sender; the sender receives only one nack instead of one per receiver. The general concept of data fusion is shown in Figure 4, in which data are processed as they traverse the network, and such processing reduces the aggregate data size. This differs from current networks, in which all data are transferred to a central location before they are processed, potentially resulting in large amounts of redundant data transfer and unnecessary load on the network.

Load Decreases as Final Result Travels to Destination

Figure 4: Data from many sources (S) are fused as they are processed along their route to the destination (D), resulting in reduced load

The reference model for active networks is comprised of a set of nodes, not all of which need be active, connected by a variety of technologies. Each active node runs a node operating system and one or more execution environments as shown in Figure 5. The node operating system (NodeOS) are responsible for allocating and scheduling node resources. Each execution environment implements a virtual machine capable of interpreting active packets arriving at the node. Several execution environments have been developed with different capabilities. For example, some may be completely general—that is, Turing complete—while others may allow only very limited execution. The set of programs running within execution environments across the network comprise an active application. This very general reference model allows for a wide variety of network service models, including those supporting a mixture of both active and nonactive traffic.

Some of the underlying assumptions are that the unit of multiplexing within the network is a packet. Another underlying assumption is that the primary function of the active network is communication and not computation. Computation may occur, but the primary benefit of such computation must be in support of communications. Assumptions regarding underlying technologies need to be minimized since the reference architecture should allow for active networking on top of any lower-layer technology. Another assumption, common to any large Internet architecture, is that administration of individual nodes may be under the control of an organization, but no organization controls all active nodes. Thus, the issue of trust among administrations will vary, and security is a primary issue.

The objectives of the architectural framework document are to specify the minimal amount of information needed to operate active components without overspecifying, or constraining, innovative solutions. Some of the objectives explicitly stated in the reference architecture document are to minimize the amount of global agreement required and to enable dynamic modification of those aspects that do not require global agreement within the network. In addition, the active network should be compatible with, and allow implementations of, current standard forwarding techniques. In other words, the active network should allow architectures with processing speeds at least as fast as today's architectures permit. Another objective is the

Figure 5: Active applications (AAs) reside on the execution environment (EE), which reside on the NodeOS

ability to scale to very large global networks. Finally, network management, at all levels, must be supported.

The distinction is made between node and network architectural issues. Node issues deal with how packets are processed and how local node resources are used and managed. In contrast, network architecture deals with global matters such as addressing and end-to-end allocation of resources. The active network is comprised of three main components—namely, the node operating system, an execution environment, and active applications. The execution environment reveals a programming interface or virtual machine controlled by active packets entering the node. The execution environment has been compared to a UNIX shell program. Note that multiple execution environments may be present on a single active node.

The node operating system manages resources of the active node and mediates demands from the execution environments that it supports. These can include things such as transmission, computation, and storage. This allows the execution environments to focus on supporting the active packet programs without having to be directly concerned with limited resources on the node or negotiating with other execution environments on the same node for resources. It is noted that an identifier, which indicates the user making the request, may accompany execution environment requests for service. This information allows requests for resources to be granted within the limits of the quality of service for that particular user. The reference architecture uses the term *principal* to designate any entity whose actions can be authorized. The principal may be a user or another active network component, such as an execution environment.

Explicit mention is made of a distinguished management execution environment responsible for the critical operations local to the node such as configuration and policy control. Such management functions acting through the management execution environment require strict security. Figure 6 shows the architectural components in more detail.

General processing of packets occurs when packets arrive at an active node, as shown in Figure 7. Information in the header of the packet specifies both protocol processing and the type of execution environment capable of handling that packet. It is the execution environment that announces its ability to handle certain types of packets through the creation of a channel. Classification

Figure 6: The interface between the NodeOS and execution environments shown in greater detail

Figure 7: Classification of packets occurs in channels within the node operating system. Packets may flow through an EE for processing. (ANEP = active networking encapsulation protocol; UDP = user datagram protocol)

of the packet and subsequent determination of the type of execution environment suitable for that packet occurs within the channel. Packets entering the node that cannot be classified or that match no pattern suggesting a resident execution environment are dropped. Execution environments, after executing any active code within the packet, transmit resulting packets through output channels. The output channel can include the implementation of scheduling algorithms. It should be noted that there is not an assumed one-to-one correspondence between input and output packets. Input active packets may reside within the execution requirement without leaving the node. In addition, packets may be spontaneously generated from a node, without corresponding input packets. In other words, it depends on the active code remaining on the node from prior packets. Another possibility is that packets may be aggregated and sent as a combined packet; again, this is a function of the code within each of the active packets working together.

It is up to the node operating system to ensure that a misbehaving execution environment does not consume all the node's resources. Scheduling mechanisms in the active networking environment must be more sophisticated than in legacy systems. This is because computation time must be taken into account as well as transmission time. It is suggested that input channels be scheduled only with respect to computation, and output channels must be scheduled with respect to both computation and transmission. This divides bandwidth equally among the set of classes.

The active networking encapsulation protocol (ANEP) is used to embed active network packets over other media. It includes a header with a type-identifier field. Well-known type IDs are assigned to particular execution

environments. It is the TypeID that allows the channel to route incoming active packets to the proper execution environment. Note that legacy packets—that is, those that do not contain an ANEP header—are also processed if the appropriate channels are set up. A common example is an execution environment that mimics IPv4 forwarding behavior. Another is an execution environment that provides enhanced TCP services, which may transparently change header bits. Note that the ANEP header also allows an indication of what the node should do with regard to error handling, for example, when an execution environment within a particular node cannot process the packet. The ANEP header would indicate whether the packet should be dropped or attempt to forward it via other means. In addition the ANEP header contains suggested security measures. It is likely to be impractical for every node in the network to authenticate every packet passing through it. However, it may be feasible for a packet to be authenticated once when it initially enters the network and afterward be verified node-to-node using shared keys between neighboring nodes. The ANEP header is thus a good location for holding a node-to-node credential.

An execution environment defines a programming interface for a virtual machine that can be controlled by sending the appropriate code instructions to it within active packets. The function of this machine is left open—that is, the architectural framework does not define it. It is the NodeOS that provides a basic set of capabilities that can be used by the execution environments to implement the virtual machine. A variety of EEs have been constructed and tested; some are universal machines—that is, they can be programmed to simulate other machines—all others offer more restricted programming interfaces that allow the user limited program capability. The reason for

limited program capability is to maintain communication efficiency and keep the focus on enhancing transmission rather than on general programming.

An active application is comprised of code running within execution environments that provides an end-to-end service within the network. Thus, it is the active application that provides the customized services for end-user applications. The active network framework allows for both active code carried in packets along with the data or code that is installed within EEs using out-of-band techniques. The out-of-band loading of new code within EEs may happen during a separate signaling phase or on demand when a packet arrives. Great pains have been taken within the active network framework architecture to minimize constraints and to enable the composition of active applications. For example, it should be possible for users to access multiple active applications and combine them in flexible ways, for example, mobility and multi-cast even though these are separate active applications.

Deployment of new EEs requires that the application-programming interface to the EE be specified so that active applications can be built. In addition, the well-known ANEP packet types supported by the EE must be made public. The active network framework architecture does not specify a standard method for installing new execution environments on an active node. In addition, the active network framework architecture does not provide a standard for inter-EE communication. Such communication can occur by packet transfer between EEs on the same node or by shared memory, known as small state.

The typical high-speed networking router/switch accepts packets on an input port, parses and validates the packets on the input port card, looks up the destination address in a forwarding table, and then sends the packet through a switch fabric to the appropriate output ports as shown in Figure 8. It is the output port card that handles encapsulation for the link and queues and schedules the packet for transmission. An active device would require general-purpose processor cards to be incorporated into this mechanism so that active packet code can be executed as shown in the bottom portion of Figure 8. Ideally, packets entering the input port would also be entering the previously defined active network channel

and be forwarded by the switch fabric to the appropriate execution environment residing on a separate processor card. This architecture will allow legacy packets to be cut through the switch fabric, bypassing the active network processor if desired. This approach is scalable because more processing cards and port cards can be added. It is recognized, however, that the NodeOS using this technique becomes a distributed operating system. Global state must be shared across multiple processing cards. This increases the complexity of the operating system, requiring additional synchronization and multiple access techniques. It is also noted that the execution environment in this architecture is physically separated from the output port cards. This limits direct access from the execution environment to the output queues. The alternative architecture divides the processing between input and output cards while leaving the switch fabric untouched. However, dividing the execution environment into separate input and output processing again causes distributed operating system problems, such as coordination between the input and output execution environment processing.

A significant concern is the potential waste of resources by erroneous or malicious active packets. Thus, mechanisms must be in place to drop packets using too much processing time. In addition, all scheduling algorithms must be work-conserving. This means that packets must be scheduled for execution in such a manner that the processor is not delayed. In general, it is very important to have a precise quantification of resources. The bit is assumed to be the universal quantitative measure of information transmission. Similarly, the byte is understood to be a measure of storage capacity. In addition, the time dimension should be added to provide a bound on the effect of storing a byte indefinitely. Quantifying computational requirements with respect to communications is an open issue and has been one of the key analytical challenges in active networks (Galtier et al. 2001). This topic is discussed further in the section on "Analysis of Active Networks." Techniques for quantifying computational resources have included removing loops from code destined to an execution environment. This allows the size of the packet to be proportional to the amount of processor time required to execute the packet. Another technique for quantifying computation involves the use of algorithmic information theory and Kolmogorov complexity. The intuition behind the use of this technique is to consider the descriptive complexity of code to be executed.

Another open issue concerns the division of labor between the execution environments and the NodeOS. Specifically, information placed in the NodeOS provides a common repository for all execution environments residing on the same node, whereas the same information placed within each execution environment on the same node would be redundant. However, placing all functionality in the NodeOS increases the complexity of the NodeOS.

Given that every node may not support every possible execution environment, a default routing mechanism should be in place for active packets, as illustrated in Figure 9. One possibility for making an active packet more ubiquitously executable is to place multiple versions of code within the packet, one for each possible

Figure 8: Active network hardware allows packets to be switched through a general-purpose processor before leaving the hardware

Figure 9: Active and current node interoperability may be achieved by enabling active nodes to mimic legacy nodes

execution environment. Because this could make packets prohibitively large, the active network framework document encourages the universal deployment of only a small number of execution environments.

ACTIVE NETWORK ARCHITECTURE

All nodes within the active network provide a common base functionality, which is defined by the node architecture. The node architecture deals with how packets are processed and how local resources are managed. The network architecture deals with global matters such as addressing, end-to-end allocation of resources, and so on; as such, it is tied to the interface presented by the network to the end-user. The node architecture is explicitly designed to allow for more than one such “network application programming interface (API).” Several factors motivate this approach. First, multiple APIs already exist, and given the early state of our understanding it seems desirable to let them “compete” side by side. Second, it supports the goal of fast-path processing for those packets that want a “plain old forwarding service.” Third, this approach provides a built-in evolutionary path, not only for new and existing APIs, but also for backward-compatibility: IPv4 or IPv6 functionality can be regarded as simply another API.

The functionality of the active network node is divided between the execution environments (execution environments or just “environments”) and the NodeOS. The general organization of these components was shown in Figure 5. Each execution environment exports an API or virtual machine that users can program or control by directing packets to it. Thus, an execution environment acts like the “shell” program in a general-purpose computing system, providing an interface through which end-to-end network services can be accessed. The architecture allows for multiple execution environments to be present on a single active node. However, development and deployment of an execution environment is considered a nontrivial exercise, and it is expected that the number of different execution environments supported at any one time will be relatively small. The NodeOS provides the basic functions on which execution environments build the abstractions presented to the user. As such, it manages the resources of the active node and mediates the demand for those resources, including transmission, computing, and storage. The NodeOS thus isolates execution environments from the details of resource management and from the effects of the

behavior of other execution environments. The execution environments in turn hide from the NodeOS most of the details of interaction with the end user. To provide adequate support for quality of service, the NodeOS allows for allocation of resources at a finer level of granularity than just execution environments.

When an execution environment requests a service from the NodeOS, an identifier (and possibly a credential) accompanies the request for the principal on whose behalf the request is made. This principal may be the execution environment itself, or another party—a user—in whose behalf the execution environment is acting. The NodeOS presents this information to an enforcement engine, which verifies its authenticity and checks that the node’s security policy database as shown in Figure 6 authorizes the principal to receive the requested service or perform the requested operation.

Execution Environment

An EE defines a virtual machine and “programming interface” that is available to users of the active network. Users control that virtual machine by sending the appropriate coded instructions to the EE in packets. Execution of these instructions will in general cause the state of the EE and the active node to be updated, and may cause the EE to transmit one or more packets, either immediately or at some later time. The function of the virtual machine provided by any EE is not defined by the architecture. The NodeOS provides a basic set of capabilities that can be used by EEs to implement a virtual machine. Thus, the EE defines most aspects of the network architecture.

EEs allow users some control over the way their packets are processed. If an EE implements a universal virtual machine—that is, one that can be programmed to simulate other machines—a user may provide a complete description of required packet processing. Other EEs may supply a more restricted form of programming, in which the user supplies a set of parameters and/or simple policy specifications. In any case, the “program” may be carried in-band with the packet itself, or installed out-of-band. Out-of-band programming may happen in advance of packet transmission or on demand, upon packet arrival; it may occur automatically (e.g., when instructions carried in a packet invoke a method not present at the node, but known to exist elsewhere) or under explicit user control.

An interesting feature of some EEs is that of SmallState, a named cache that enables SmartPackets to leave information at a node that can be retrieved later by other SmartPackets. SmallState thus becomes an interpacket communication (IPC) mechanism, providing a mechanism for packets to talk to each other and implement collaborative behavior in the network. The extent of the IPC depends on the control mechanisms defined by the EEs for their SmallState. In some EEs, like Magician, SmartPackets explicitly create, modify, and destroy SmallState. Access policies are defined for SmallStates at the time of creation. This includes defining access-control lists or access masks for accessing, reading, and writing SmallState.

Node Operating System

It has already been mentioned that the overall architecture of an active network is comprised of three layers of code: the node operating system at the lowest level, one or more EEs, and at the top level the active applications. It is assumed that the node operating system would handle multiplexing the node's internal communication memory and computational resources of packet flows that cross the node. EEs define the programming language in which the active packet's code is written. It is the active applications that provide the end users with their network services.

The following three high-level design goals are explicitly stated in the node operating system architecture document, namely, that the NodeOS interface primary role should be designed around supporting network packet flows—namely, packet processing, resource utilization, and admission control—done on a per-flow basis. It is also recognized that flows themselves can be defined at different granularities—for example, port-to-port flows, host-to-host flows, application flows, etc.; thus, there is no assumed single definition of a flow. It is also not assumed that all implementations of the NodeOS will export exactly the same set of features. Some implementations will have special capabilities that the EEs and their associated active applications may desire. Finally, whenever the NodeOS requires a mechanism that is not particular to active networks it should borrow from established operating system interfaces.

The abstractions defined for the NodeOS are important to understand. These consist of thread pools, memory pools, channels, files, and domains. The domain is the primary abstraction for accounting, admission control, and scheduling, as shown in Figure 10. Each domain contains the resources needed to support a packet flow.

Figure 10: An example of domains to control resource usage in the active node

The domain typically contains a set of channels on which messages are received and sent, memory pools, and thread pools. Remember that the EE, using threads, processes active packets arriving on the input channel, and memory is allocated to that domain, and the packets are then transmitted on an output channel. Thus, a channel consumes not only network bandwidth but also CPU cycles and memory. Thus, intuitively, the domain encapsulates the resources used across both the NodeOS and the EE on behalf of a packet flow. Domains will be created in the context of existing domains, so they can be thought of as a hierarchy with the root domain corresponding to the NodeOS itself.

Note that a domain can create a subdomain in order to more finely encapsulate individual flows with resources. The thread pool is the primary abstraction of computation. Example parameters that are specified in creating a thread pool include the maximum number of threads, the scheduler to be used, the cycle rate at which the thread pool is allowed to consume the CPU, the maximum length of time a thread can execute, and a stack size for each thread, etc. Threads execute on an end-to-end basis—that is, the threads cut across the NodeOS up to the EE. This allows record keeping of resource usage for a flow.

The memory pool is the primary abstraction of memory. Such memory can implement packet buffers as well as hold an EE-specific state. Whenever memory or processing by the EE becomes excessive—that is, if the resources are overused—the NodeOS will warn the EE of the situation, and if the EE does not correct the situation the entire domain will be destroyed.

It is the domain that creates the channels discussed previously in the active network framework architecture, to send, receive, and forward packets. The distinction is made between anchored channels and cut-through channels, as illustrated in Figure 11. Anchored channels are used to send packets between the EE and the underlying communication substrate. Anchored channels are further characterized as either incoming or outgoing. Cut-through channels forward packets through the active node, without being intercepted and processed by an EE. Note that the EEs still allocate the cut-through channels.

When creating the channel, the domain must specify which arriving packets are to be delivered on this channel,

Figure 11: Anchored and cut-through channels through the node operating system (ATM = asynchronous transfer mode)

a buffer pool to hold the packets, and a function to handle the packets. The packets to be delivered are described by an address specification string and a demultiplexing key. When creating an out-channel, the domain must specify where the packets are to be delivered and how much link bandwidth the channel is allowed to consume.

It is possible that an EE wants to demultiplex multiple packet flows out of a single protocol. The demultiplex key specifies this information, and it consists of typical network components such as offset, length, value, and mask. This demultiplex key is compared to the payload of the packet, thus allowing precise pattern specification of which packets should be sent on which channels.

A suggested nomenclature for the formation of channels uses the protocol components separated by a slash. An example would be “IF.0/IP/UDP/ANEP,” which specifies that packets tunnel through IP. Another example would be “IP/IF,” which specifies outgoing IP packets. Cut-through channels would have a syntax using a pipe symbol to denote transition from incoming packet processing to outgoing packet processing. An example would be “IP/UDP|UDP/IP.” In addition, packet addresses and port numbers may be used to further specify packet flows. Note that the cut-through channels allow the NodeOS to forward packets without the involvement of either an EE or an AA. In summary, channels and domains support a flow-centered model. The domain encapsulates the resources that are applied to a flow, while the channel specifies packets belonging to the flow and the functions that are applied to the flow.

Files are the abstraction for persistent storage and coarse-grained sharing of data. The files intuitively follow the common concept of a file in an operating system. The node architecture document goes to the point of specifying the actual names of individual function calls.

To provide for quality of service, the NodeOS has scheduling mechanisms that control access to the computation and transmission resources of the node. These mechanisms isolate, to some degree, one user’s traffic from the effects of other users’ traffic, so that each appears to have its own virtual machine and/or virtual link. When channels are created, the requesting EE specifies the desired treatment by the scheduler(s).

Such treatment may include:

- Reservation of a specific amount of bandwidth (transmission or processing) and isolation from other traffic
- Isolation from other channels’ traffic and guarantee of a “fair share” of available bandwidth; the available bandwidth is divided more or less equally among all channels in this class.
- Best-effort—that is, no isolation from other traffic in this class.

The NodeOS may deny requests for channels with the first two types of service when resources are in high demand. Note that input channels are scheduled only with respect to computation, while output channels are scheduled with respect to both computation and transmission.

Active Networking Encapsulation Protocol

The ANEP defines a method by which active packets may be transmitted over different media. The ANEP implements the objectives within the active network framework document by supporting the coexistence of different EEs and the multiplexing of received active packets through the different channels. The active network encapsulation protocol defines a header. The primary reason for the header is to allow quick determination of the environment required to support execution of the active code within the packet—in other words, to identify whether the correct EE exists for the received packet. The header also provides some indication of the fault processing if the EE does not exist on the node. The header also has room for security information. The format of the ANEP packet, similar to most protocol packets, contains the version, flags, type ID, header length, packet length, options, the largest portion which is the payload, namely the active contents itself. In this description we focus on version 1 of ANEP, shown in Figure 12.

The type ID field indicates the environment required for execution of the active packet. The Active Networks Assigned Numbers Authority (ANANA), which is similar to the Internet Assigned Numbers Authority (IANA), maintain type IDs. TypeID zero is reserved for possible future network layer error messages. If a particular node does not recognize the type ID, the most significant bit of the flag field should be checked to decide how to handle the packet. If the most significant bit of the flag is 0, the node should try to forward the packet using the default routing mechanism, by checking information available in the options part of the header. If the most significant bit of the flags field is 1, the node should discard the packet. The ANEP header length field specifies the length of the ANEP header in 32-bit words. Finally the ANEP packet length field indicates the length of the entire packet in octets.

The options portion of the packet is in the form of type, length, and values (TLV). Values used are maintained by the assigned numbers authority, which also maintains the option type field. Other entities can use their own values if the most significant bit of the flags field, bit 0, is set. These options are meaningful only inside the indicated EE, so it is up to the type ID owner to specify these values. The option length field contains the length of the TLV in units of 32-bit words. This includes lengths of the flags, option type, option length, and option payload. There exist predefined options indicated as follows. The source identifier error option uniquely identifies the sender

Figure 12: The active network encapsulation protocol packet structure

of the packet within the active network. It contains a 32-bit value, which identifies the addressing scheme in use, followed by the actual address. The scheme identifiers have been predefined as IPv4, IPv6, and 802.3. The destination identifier is an option that uniquely identifies the destination of the packet within the active network. This is the final destination, not an intermediate route. The format is the same as that for the source identifier option. Active nodes whose EE is not available might use this field. Another option is the integrity checksum. The value of this field is the 16-bit ones complement of the ones complement of the entire ANEP packet, starting with the ANEP version field. Another option is the non-negotiated authentication. This option is used to provide one-way authentication. It assumes no prior negotiation between the packet originator and processing nodes. It has the 32-bit value that identifies the authentication scheme in use followed by the data. The following authentication mechanisms have been predefined SPKI and X.509. Additional values may be used by agreement of the assigned numbers authority.

End-to-End Considerations

Let us take a step back and consider the arguments opposed to active networking, then address them one by one. End-to-end arguments have suggested that functions placed at low levels of the system may be redundant or have little value when compared with the cost of providing them. Examples have been shown that include bit error recovery, security using encryption, message suppression, recovery from system crashes, and delivery acknowledgments. Essentially, the prescription is to move functionality upward within a system, that is, toward upper layers. It is said that the function in question can completely and correctly be implemented only with the knowledge and help of the application standing at the end points of the communication system. Therefore, attempting to provide that function within the communication system is not possible. This is known as the “end-to-end argument.” Examples are given in which placing functionality within the network is either redundant, overly costly, or not useful. End-to-end arguments are often used as an Occam’s razor when it comes to choosing functions to be provided in the communication subsystem. It is interesting to note the use of Occam’s razor in the above, since it is also used in determining the shortest packet code, described in section “Analysis of Active Networks” via Kolmogorov complexity. The principle states that “entities are not to be multiplied beyond necessity.” In other words, *all things being equal, the simplest explanation is the best one.*

The following are key principles regarding the end-to-end arguments: Some services require the knowledge and help of the end system and thus cannot be implemented entirely within the network; if all applications do not make use of the service it should be implemented in such a way that only those applications using it have to pay for it; and finally, the amount of support for any given end-to-end service in the network is an engineering trade-off between the performance and the cost of implementing the service. Active networks actually support these

principles, rather than violate them. Active networking requires that the interface to such functionality be carefully designed, the costs and benefits of each service be computed, and engineering trade-offs be carefully evaluated. In fact, some services can best be supported and enhanced using information that is available only from within the network. The network may have information that is not available to the application, and the timely use of that information can significantly enhance the service seen by the application. It is precisely these situations in which active networking shows significant gain and support of the end-to-end argument.

Note that the end-to-end argument was originally made with respect to a view of the network as a monolithic entity attempting to provide a single optimal quality of service to all users. Active networks actually increase the likelihood that services will be differentiated and useful to specific users. In fact, a market-driven approach will cause developers of active applications and users to be keenly aware of the costs involved and thus use and implement only what are necessary for particular applications. In effect, the active network is a framework for accelerating implementation of the end-to-end argument. As long as active networking provides cut-through capabilities to support at least services with current performance then active applications can be developed on a case-by-case basis.

A common mantra chanted by Internet developers is to keep the network simple, to avoid complexity. Although this is an admirable and useful goal, a significant challenge is that quantitative measures of simplicity and complexity are lacking. Thus, it is impossible to say definitively which architectures are simple and which architectures are complex. There is no way to prove that the Internet is simple and active networks are complex, except perhaps by using some ad hoc measure such as what “looks” or “feels” simple to a particular individual or small group with a particular common experience or background.

Security

Active packets contain code or references to code. The EE will extract code from the packet and execute the code on the node in which the packet resides. The result can be a modification of the state of the node, modification of a packet, or the transmission of packets. Legacy packets such as IPv4 or IPv6 may be forwarded before or they may receive services provided by the active network itself. Recall from the NodeOS framework that a domain may create a subdomain at any time. The principal assigned to a domain established at creation time governs activities of the domain. Note that the node begins operation with one or more domains assigned to EEs. Thus, an EE is permitted to start subdomains with more finely grained packet filters, as it desires. Therefore, the EE makes its own decisions as to whether the active code and a packet will run as part of the EE’s domain or in some separate domain with the packet’s principal privileges and separately allocated resources.

Consider what happens when an active packet arrives at a node. It is assigned by the node to an in-channel of

the domain, either anchor or cut-through, and is processed. If the active packet processing occurs within the EE, then the active code has access to the EE's services and resources. The EE interface might pass the NodeOS interface through to the active code or might replace or augment that interface with its own services. It is possible that output packets may be created, in which case, resulting active packets are transmitted on an output channel. Remember that these output packets might have been forwarded in input packets, been modified in the packets, or been forwarded in newly created packets. It is also possible the processing of the packet's active code may result in changes to the state of the node or the EE.

The security paradigm within active networks uses abstractions, or models, comprised of actions taken by subjects upon objects. Each object must be authorized to take a specific action upon a specified object. Attributes of the subject, object, and an action can be compared to determine whether the action is authorized. If the authorization is valid, the operation may take place; if the authorization is invalid, operation is denied. The security policy is comprised of the valid authorizations.

The security policy is enforced by a particular component or subsystem. The policy specifies the subject and object attributes that must be compared and whether a valid match has occurred allowing the action to take place. The component must enforce the security policy to protect the resources for which it is responsible.

Subjects are the actors in the security model. The previously mentioned security policy determines what the subject is allowed to do. As a specific example, an active application is the subject when it requests that an EE run code. An EE is a subject when it requests a NodeOS to allocate a channel.

Objects are entities for which use must be authorized. Authorization is required in order to provide confidentiality and integrity and, for example, prevention of denial-of-service. The attributes associated with the particular object depend on the type of object to any entity, which provides access to that object. There are many types of objects within the active network, some of which include the NodeOS resources, such as thread pools, memory pools, channels, files, domains, etc. These object attributes would include file ownership and permissions and current resource pool usage. Other objects with the NodeOS may represent services such as reboot, control of an EE, and packet routing. These are obviously critical services and require strict authorization checks. EE objects include e-resources such as access to persistent state—that is, small state. Other objects include services, and these could include such things as rebooting the EE, stopping the EE, and controlling the active application. These are also critical services and should be available only after proper authorization. Finally, active applications are also objects. It is possible that an AA may be the object of another AA; in other words, one AA may perform an action upon another. This may include actions such as halting execution of the AA and sharing data among active applications.

Recall that actions are operations performed by subjects upon objects. Actions are dependent on the type of object and the resource provider; not all actions

are relevant to all objects. The available actions should be defined within the API of each resource provider.

There are many entities within the active network whose assets need to be protected. These include the end user at the source and destination nodes, active nodes themselves, EEs, the active code within the active packets, and the domains within the active nodes. It is interesting to note that the active code—that is, the code within the active packet—stands as a proxy to the end user who launched the packet. Thus, it has the same security concerns that the end user would have. This may include things such as access to the domain in which it is executing and access to the sharable persistent state that it may create.

The types of attacks to be expected in an active network can be extrapolated from the attacks seen on traditional networks. These include: (1) unauthorized disclosure, which is countered by authorization and confidentiality services, (2) attacks resulting in deception, which are countered by integrity, authentication, and nonrepudiation security services, (3) destruction or denial of service, which are countered by authorization and integrity services, and (4) usurpation, to be countered by authorization, integrity, and confidentiality security services.

The security framework document concentrates on the enforcement of authorization policy to counter the previous threats. The sender of the active code, which has access to cryptographic operations in each node, controls confidentiality of the active packet payload.

Therefore, the major components of the active network that have resources requiring protection are the node itself, the EE, the sender of the packet that is being processed, and the active code that is executing in the node, as shown in Figure 13. The node is clearly interested in protecting itself; without survival of the node, nothing running on the node can be guaranteed to have integrity. The node needs to protect its resources from unauthorized usage threats to the node that can arise from EEs running on the node that may modify the node state or view sensitive node information. In addition, the sender of active packets who may maliciously send packets in such quantity as to exceed node resources potentially threatens the node. In addition, the node is susceptible to attack from active code within active packets, which may

This Column: Can See Threat From:

	Packet	Code	EE	Node
Sender		Yes	Yes	Yes
Code	Yes	Yes	Yes	Yes
EE	Yes	Yes	Yes	Yes
Node	Yes	Yes	Yes	

This Column: Can Be Protected From:

	Packet	Code	EE	Node
Sender	N/A	Yes	Not Really	Not Really
Code	Yes	Yes	Not Really	Not Really
EE	Yes	Yes	Yes	Not Really
Node	Yes	Yes	Yes and No	N/A

Figure 13: Active network components and their potential sources of threat (N/A = not applicable)

also consume resources or modify the node state or view sensitive node information, etc., while executing within the EE.

The EE must protect itself. Threats to the EE come from senders of packets and from active code running within it. The EE also sees possible threats from the node on which it resides. It is assumed that there is little defense that the EE can provide for itself from the node on which it resides; thus, before any EE is placed on the node, the administrator that distributes the EE must ensure that the node is secure.

The sender of the active packet is assumed to be interested in protecting the information, either active or passive, within the packet. Specifically, the sender is assumed to be concerned about the integrity and confidentiality of the information. The sender of the packet may perceive threats from other active code in the node, from the EE and from the node itself. Through cryptographic means, the sender protects the information from source to destination. Unfortunately, if the active packet must be decrypted in order to run on the node, for example, then the sender of the packet cannot protect it from the node or the EE. In this case, the sender must rely on the ability of the active code to avoid nodes and EEs that are not secure.

The active code is highly dependent on the packet in which it resides. This code may be able to create a state that can be shared with other active code or provide services to other active code. It is this code that wishes to protect itself, to protect a shared data and packet payload from unauthorized modification, or to protect its services from unauthorized use and to protect its resources against unauthorized consumption. The active code sees potential threats from other active packets, for other active code, from the EE, and from the node. It is conceded that the active code cannot protect itself against the EE and the node, which is executing. Thus, it must ensure that it does not forward itself to either unsecured nodes or unsecured EEs.

In the case of authorization, we need a language in which the authorization policy is expressed, a way of representing the principal being authorized, and mechanisms to ensure the authenticity of the claim to principal identities and the integrity of the packet. The language for the authorization policies may be simple access control lists. See the work done in Policy-Maker and Keynote (<http://www.dmtf.org/education/academicalliance/pilz.pdf>, KeyNote; <http://www1.cs.columbia.edu/~angelos/keynote.html>), which are two related efforts to offer sophisticated policy expression capabilities. The Seraphim active capabilities have full Turing expressibility.

It is recognized that conflicts may occur in the expression of the security policy. For example, the creator of an object, the sender of an object, and the node in which the object is stored may have conflicting security policies for the same object. Thus, there should be a uniform way in which access to these objects is controlled. Resolution of conflicts can occur by a predefined compositional logic, prioritization that is setting precedents among the policies, and having a configurable meta-policy. The node should have a final determination as to how composition of policies will be performed.

Hop-by-hop protection is needed to ensure the communication and signaling between neighboring active nodes. Always keep in mind that not all nodes will be active nodes; however, neighboring nodes must somehow be identified so that the keys can be shared to protect the Internet communication. End-to-end protection of packets requires cryptographic techniques, which can be divided into two types: asymmetric and symmetric. Asymmetric techniques require that only the originator be trusted. Only the entity holding the private key can verify the originator's identity associated with the key. However, if the packets change in a node, the digital signature will fail the next verification. Attempting to share the private key with the receiving node so that it can recompute the digital signature with the changed contents would cause the private key to be shared with many other nodes, defeating the privacy of the private key.

Symmetric techniques would solve the problem of allowing intermediate nodes to recompute the digital signature of the packet. However, installing keys to each node of a packets' path through the network would greatly broaden the trust model. This model depends strongly on the method of key distribution. It is possible that a symmetric key could be distributed by an active application. It should be noted that distribution of symmetric keys are expensive in terms of processing and latency and that it is important that the active packets requiring the key follow the precise path through which the keys have been distributed. If keys are distributed by an active application, this application must be secure. Also note that a symmetric key could be distributed at the NodeOS level by signing the key at the originating point and encrypting the signed key hop-by-hop for the neighboring node. This means that all nodes receiving the key can produce a packet that looks like it is coming from the originator. This key distribution technique allows the nodes to protect applications that are not secure, since this is done at the NodeOS level.

The active packet is divided into two areas: the area containing the code and an area that may vary. The digital signature covers the static area only, leaving the variable area unprotected. Symmetric techniques can cover either the static area, the variable area, or both.

Recall that a principal in the security architecture is an entity that can make a request subject to authorization. Examples of attributes of code can include the author or vendor, quality attributes like "virus-free" or "ISO-9000," or proof-carrying code. In order to trust such an attribute, it needs to be certified by some trusted authority. The cryptographic association in the form of a code credential is used to provide a binding between the code and its attributes. In fact, given the dynamic nature of an active network, the attributes are added to a packet as it traverses a network. References to the code could be placed within the variable portion of the packet. The packet structure must support lists of credentials and the separation of static and variable packet payload in both asymmetric and symmetric cryptographic authentication.

Responsibility for authentication of packets is placed in the NodeOS because these functions are of common use to all EEs, the NodeOS, which has resources of its

own to protect, requires the functionality itself, and cut-through channels would be difficult to protect if the authentication support were in the EE.

Whenever active code executes on a node, there must be a component that is responsible for binding the security context to the execution of code such that the context is available to authorized management entities but not to the executing code. Enforcement includes intercepting requests for access to an object, extracting the security context, retrieving policy for the context, object, and request, evaluating the policy, and composing evaluation of separate policy components if necessary.

It is helpful to think about the security events involved as an active packet progresses through the network. First, the hop-by-hop key identifier is pulled out of the packet and used to retrieve the appropriate key, algorithms, etc. The hop-by-hop integrity is checked, and failure causes the packet to be dropped. Next, the packet is matched to a domain filter. Then, the list of credentials is extracted and retrieved, and credentials are verified. If any credential fails the verification process, the packet processing will continue, but using only those credentials that succeeded. Next, the NodeOS checks the authorization of the EE to be receiving this type of packet, then the NodeOS checks the authorization of the domain to be receiving this type of packet, then the NodeOS checks the packet's authenticated identity according to the authorization policy of the domain. At this point, the ANEP header and hop-by-hop integrity fields have been used and are no longer needed; thus, the packet is stripped of these components. The code is extracted from the packet or retrieved if necessary. The code could be within the packet, reside in the code cache, or stored within another node. It is assumed that the retrieval process for the code will have its own security protections. Next, all of the authenticated credentials are bound to the domain's execution in a security context. Finally, the domain can begin execution of the active packet code.

The code may attempt access to another active application's resources. This can be mediated by the EE. Packets sent by the domain are cryptographically protected by the NodeOS and packets transmitted by the NodeOS have hop-by-hop integrity applied. It is also possible that code may call for a new subdomain to be created. When creating a new subdomain, the active code

must specify which packets are authorized for processing in the new domain.

An interesting problem with active networks resides around revocation not only of privileges, but also of active code. It must be possible to revoke code that has been previously distributed throughout the network. Revocation notices are sent in anticipation of or in response to suspicious activity within the network, and such notices are propagated using active mechanisms. It is possible for a node to be executing a revoked piece of code between the time the revocation is issued and the time the distribution reaches the node. Note that revocation notices are objects in their own right. The NodeOS affords the best opportunity to apply revocation notices.

It should be noted that active networks provide the capability for innovative new security paradigms. Although a traditional node cannot recover if it does not have all the security information necessary to authorize an incoming request, an active node could encapsulate an unauthorized packet with a protective wrapping to monitor its activities.

IMPLEMENTATIONS OF ACTIVE NETWORK COMPONENTS

Execution Environments

There are a number of EEs developed for active nodes to study various issues such as resource allocation, service composition, and security. This section discusses features of execution environments. A few popular EEs are listed in Table 1. Note that Caml is a strongly typed functional programming language from the meta language (ML) family of languages.

Researchers developed many different EEs that concentrated on particular facets of active networking mechanisms. This provides an opportunity to enumerate and classify properties that execution environments possess to make code transport and execution possible. This section discusses the following principal features of EEs:

- Code download
- Implementation platform and language

Table 1: Execution Environments

EE Name	Institution	VM Platform	Approach
ANTS	Massachusetts Institute of Technology (MIT)	Java	Capsule
CANeS	Georgia Tech	Unity	Capsule
Magician	University of Kansas	Java	Capsule
NetScript	Columbia University	Netscript	Discrete
Switchware	University of Pennsylvania	Caml	Hybrid
SmartPackets	BBN Technologies	Assembly code	Capsule

- Composition
- Security and authentication
- Resource allocation and monitoring
- Interpacket communication

The vision of active networks is that of a framework of networking components from which services are composed to provide users with a flexible, customizable networking infrastructure. Active networks will allow the composition of user-injected services with those that are preconfigured at the network nodes, enabling users to develop highly customized solutions in the network to handle their application data. The EE has to be able to provide modular service components for users to draw on as building blocks. Users will compose their own custom framework by using the “glue” provided by the EE in which their code will execute. The glue can be in the form of library modules, a scripting language, or an API.

The glue language itself can be a high-level language like Java, C++, or C, or it can be a scripting language like Perl or Tcl. In this case, developers do not have to go through a learning curve, and this enables them to reuse existing code and integrate it into the active network framework. The glue language can also be custom designed for active networks.

The advantage of a custom language is that the language can be designed keeping in the mind the unique requirements of active packets and the constraints that may be imposed on their functionality. For example, SwitchWare provides service components called switchlets that are resident at the nodes for users to customize node behavior. On the other hand, Magician provides components that implement various pieces of communication functionality.

SwitchWare and NetScript use a script-like programming language that accesses the heavyweight service components. On the other hand, Magician and ANTS allow the user to leverage a high-level language like Java to compose custom services from basic components.

Components should have a formal, well-defined interface that abstracts the inner workings, yet presents the user with a rich representation of its behavior. This is defined as introspection. Introspection enables a user to access an implementation state and work with abstractions to it. This increases reusability because the component can be reused in different protocol frameworks. The property of intercession enables a user to modify the behavior of an abstraction. The user can refine existing behavior or adjust the implementation strategy to improve performance. This is usually achieved through the mechanism of inheritance in object modeling. This enables users to customize previously developed active network components, tailoring them to the needs of the application without having to write new components from scratch.

Execution environments can provide explicit security mechanisms for the execution, authentication, and authorization of packets. Minimally, EEs have to execute packets within a sandboxed environment that is protected from unintentional and malicious incursions by other

packets. In addition, EEs may implement trust mechanisms to authenticate various properties of the code contained in the packets, such as its ownership, creator, source, rights, and privileges.

ANTS: Active Network Toolkit

Written in Java, ANTS (Wetherall, Gutttag, Tennenhouse 1999) primes the package delivery path within necessary protocol code during the initial delivery only, since the packets can use code without the overhead of transporting it. This is done using capsules, which carry both code and data. In the active network toolkit active messages are called “capsules.” A unique type based on the message digest algorithm 5 (MD5) of the capsule code identifies capsules. When a capsule arrives at a node, a cache of protocol code is checked for the presence of the capsule code, which may already reside at the current node. If the code does not exist on the current node, a load request is made to the node from which the capsule originated. The originating node receives the load request and responds with the entire code. The current node then incorporates the code into its cache. Processing functions may update capsule fields and store application-defined information in the shared node cache of soft state.

ANTS provides a mechanism for protocol composition using the CodeGroup attribute of the ANTS capsule. Code belonging to the same protocol suite (or stack) shares the same CodeGroup attribute. Protocol modules are demand-loaded separately into the active node prior to capsule execution. A wrapper module (which is the main class for the protocol) puts together the protocol modules in the manner desired by the programmer. ANTS is written in Java; therefore, it supports modularity, inheritance, and encapsulation. The base implementation available from MIT does not support any security features beyond those provided by the Java virtual machine. Other groups, such as Trusted Information Systems Laboratory at Network Associates Inc., have modified the ANTS prototype to add security and authentication mechanisms.

CANes

The Composable Active Network Elements (CANes) (Bhattacharjee et al. 2002) execution environment was developed after the Architectural Framework Group and the NodeOS Working Group put together their specifications. Thus, the CANes environment is a NodeOS specification-compliant EE that sits on top of the Bowman node operating system. CANes uses a slot processing model that comprises two parts: a fixed part, also called the underlying program, that represents the common processing applied by an active node on every packet passing through the node, and an injected program implementing user-specified functionality. The injected program is bound to a specific slot, which when called causes the bound program to be executed. The underlying program provides basic services, such as forwarding, that can be chosen and that are well known and preinstalled on every active node. A set of injected programs is then selected to customize the underlying program. These injected programs can be available at the active node or they can be downloaded from a remote site. CANes thus uses a discrete approach for downloading code.

Because CANEs is built on top of Bowman, which uses the NodeOS specification, Bowman handles resource allocation and security issues. Bowman also implements the IPC mechanism, called state-store, to exchange data between packets without sharing variables. CANEs programs are written in a custom language called CANEs User Interface (CUI). It comprises distinct computation and communication parts.

The computation part is a directed acyclic graph (DAG) in which the underlying program sits at the root of the graph and the injected programs are at the leaves. The arcs in the DAG identify the slot to which the child is bound. Multiple programs can be bound to the same slot. Binding of the injected programs to the slots is done when CANEs parses the computation part. The communication part of the CUI program identifies a routing schema for the user. The user may also specify a set of classifier rules that are used to select incoming packets upon which the flow acts.

Magician

Magician is a toolkit that provides a framework for creating SmartPackets as well as an environment for executing the SmartPackets. Magician is implemented in Java version 1.1. Version 1.1 was chosen primarily because it was the first version to support serialization. In Magician, the executing entity is a Java object whose state is preserved as it traverses the active network. Serialization preserves the state of an object so that it can be transported or saved, and re-created at a later time. Magician uses a model in which an active node is represented as a class hierarchy. Every protocol is derived from an abstract base protocol. Every active node provides some basic functionality in the form of certain default protocols—for example, routing. Users may prefer to use these default protocols if they do not wish to implement their own schemes. To foster privacy and safety, a unique state is created for each invocation of the protocol.

State that is common to all invocations of a protocol is inviolable and is accessible only to users that have appropriate authorization. Providing each user with a protected copy of the state enables the user to customize state if necessary. Users are permitted to install their own protocols. A user creates a new protocol from scratch by extending the base abstract protocol. When a SmartPacket carries over the protocol to the active node, a new branch is created for that protocol. Alternatively, the user extends an existing protocol class at the active node and customizes it to implement application-specific behavior as shown by the example of a user-defined routing algorithm in the figure. Thus, the user is able to inherit certain basic properties of the parent protocol and provide minor or major behavioral modifications to tailor it to the application's requirements. In this model, the active node is thus perceived as an object with behavior that can be modified dynamically. SmartPackets are treated as objects that carry custom protocols in the form of executable code, which when installed at the active nodes, modifies their behavior to suit application requirements.

The class hierarchy model for active nodes is advantageous in many respects. It provides the user with the ability to customize default functionality at the active nodes using the extension-by-inheritance philosophy.

The inheritance model also provides default functionality for user SmartPackets that choose not to implement their own. That enables the active node to emulate behavior of traditional nodes to support transport of conventional packets. The unique state space provided to each invocation of a protocol corresponds to the instantiation of an object from its class definition. This affords privacy and safety to the SmartPacket executing in that state. It also provides an isolated, secure environment for the execution of user code so that the active node can monitor and regulate its activities. The class-model approach differs from the data flow composition model, wherein protocol functionality is activated only by data flow. In the class model, instead of data being transferred between protocol components, execution control is transferred between the protocol components. Protocol components have access to the user data and can choose to act on the data or perform other activities.

The class model also exhibits three of the five properties listed earlier, namely modularity, introspection, and intercession. Modularity is achieved by breaking down communication functionality into distinct protocol components. The functionality of the components is defined as a Java class. The property of introspection is satisfied when protocol components are designed as suitable abstractions and specified with well-defined interfaces that promote reuse. Using the principles of inheritance and aggregation, these components are brought together to form a composite that implements the functionality desired of a service to be injected in the network. This satisfies the intercession property.

NetScript

NetScript (da Silva, Florissi, and Yemini 1998) is a data-flow programming language in which computation consists of a collection of interconnected programs that process data streams flowing through them. The language supports the construction of packet processing programs, interconnecting these programs and allocating resources to them. NetScript programs communicate with each other through their input and output ports. The arrival of data at an input port triggers execution of sequential event-handling code inside the program.

NetScript is not a full-blown language, and it lacks traditional programming constructs like iteration control, functions, and data types. Therefore, the programs (called “boxes” in NetScript) themselves are written in languages such as C and Java. NetScript provides constructs for gluing together the protocol-processing boxes and thus is viewed more as a coordination language. Protocol composition is achieved by using the NetScript constructs to define and establish interconnection between the various boxes. Dynamic composition is achieved using the concept of box templates. A box template describes the input/output port signature and the internal topological structure of the dataflow program. The port signatures define the types of messages that the box accepts and generates. The topological structure describes the interconnections between the internal boxes. It is possible to create one or more instances of this box template on active engines across the network. Defining a composite box template that describes the protocol components

and their interconnections creates a new protocol framework. The protocol components themselves can be box templates or they can be primitive programs. The framework thus constructed is deployed in the network by dispatching it to individual NetScript engines at the network nodes. When a NetScript engine receives a new box template, it creates a running instance of it by examining its port specification and internal topological structure. The engine then loads and instantiates each internal box, makes appropriate connections between box ports, and starts up the new instance to allow protocol messages to flow through it. The composition mechanism is rich enough to enable composition of layered protocols or the extension of protocol components with new features. However, the extension mechanism is not as rich as the extension mechanism of an inheritance model. It is not possible to override only a few properties of a box. The box must be used with its established properties or a new box defined with the unwanted properties replaced by the desired ones.

PLAN

Switchware (Alexander et al. 1998) provides protocol composition using a two-level architecture that consists of switchlets and user programs in active packets. Each switchlet provides services in the form of methods manipulating protocols implemented for that switchlet. The switchlets' services are implemented in a high-level language and are dynamically loaded at the network nodes. Active packets are user packets that invoke the services provided by the switchlets. The code in the active packets is written in a language called PLAN (Hicks et al. 1999) specifically designed for active networks.

PLAN is a stateless, strongly typed, functional-style lambda calculus system with pointer-safe access, which addresses safety and security concerns. PLAN programs also make statements about resource needs and bounds. A PLAN program is initially assigned resource units, which are depleted as it executes or it spawns new PLAN programs. Since resource units cannot increase, they eventually are exhausted, which guarantees program termination. PLAN packets contain fields to help manage the packet: evaluation destination, resource bound, and routing function. Although PLAN is implemented in Java, the programming language PLAN provides to the user is based on ML with some added primitives to express remote evaluation. PLAN programs can allow resident data to remain on a node after the program terminates.

Table 2 provides a snapshot of some of the prominent research efforts in each of the areas outlined above. This list is by no means exhaustive. There are other internal efforts at other institutions that have not received much attention. The rest of this section provides a high-level description of the projects listed in the table on the next page.

KU SmartPackets

KU SmartPackets can operate in both discrete and integrated mode; the packets are called "datagrams" and "management" packets, respectively. SmartPackets can

leave information on active nodes after its execution environment expires. A time-to-live parameter for the cached information is assigned when the information is cached.

Spanner and Sprocket

Spanner and Sprocket are an active network assembly and high-level language, respectively. Sprocket is similar to C language. In addition, it has built-in functionality for querying Simple Network Management Protocol (SNMP) Management Information Base (MIB) object data. This would make it ideal for network management algorithm development.

Liquid Software

This EE gains speed in two ways. First, it uses Java to C translators in conjunction with C compilers, thus avoiding the need to interpret byte code at run time. Second, it uses compilers that execute quickly and can be run at the point of execution.

NODE OPERATING SYSTEMS

The vast difference in the increasing slopes between communication data rates and computational rates is pushed down to the level of the node operating system. Data rates have typically increased at twice the speed of computer processing power. For the time it takes processors to double their computing power, data rates will have increased by a factor of four. The result is that the active node operating system and its supporting hardware must be extremely intelligent regarding efficient packet processing. Thus, there has been a considerable amount of research on the development of active network node operating systems; space limitations do not allow a detailed discussion here. Instead, the goal of this section is to provide an introduction to a few active network operating systems and how they have approached the challenge of providing manageable and efficient interfaces between the active execution environments and the active node hardware. Much of this work has focused on developing paradigms, or abstractions, that facilitate development while maintaining efficiency via a tight coupling among the EE, the NodeOS, and ultimately, the hardware. Some operating systems have focused on simplicity, safety, and security, while others have chosen to focus on performance, and still others have focused on features and flexibility.

One may give the honor of being the first known active network to SoftNet (Zander and Forchheimer 1983, 1988), a programmable packet radio network developed in 1983. One might consider its Forth environment, called MFORTH (Zander 1984), a NodeOS/EE. Because SoftNet allowed packets carrying code to modify its behavior, it is consistent with the definition of an active network. However, a discussion of more recent node operating systems follows.

MIT (Tennenhouse et al. 1997) had constructed a prototype active network node infrastructure based on the ACTIVE IP option in IPv4, which enabled active packets (capsules) to be passed to a computational engine. Given that it was a prototype, Tcl was used. Most subsequent

Table 2: Research Areas

Research Area	Project	Organization
Network management	Robust Multi—Scalable Network Management (MIT)	MIT
	NESTOR— <i>NESTOR : NEtwork Self managemenT and ORganization</i> (Columbia)	Columbia University
	Active Virtual Network Management Protocol (GE)	GE Global Research
Security prototypes	Secure Active Network Prototype (NA)	Network Associates

	Dynamic Interoperable Security Mechanisms (U of I)	University of Illinois
	Active Intrusion Detection and Response (NAI Labs and Boeing)	NAI Labs and Boeing
Mobile and wireless applications	PANDA: planning and negotiation of active network agent deployment (UCLA)	UCLA
	SpectrumWare (MIT)	MIT
	MAGIC-II: Adaptive Applications for Wireless Networks (U of K)	University of Kansas
Enhanced network services	Proactive Infrastructure (UCLA)	University of California, Berkeley
	Active Web Caching (UCLA)	UCLA
	Composable Active Network Elements (GA Tech)	Georgia Tech and University of Kentucky
Quality of service	Active Network Applications (U of W & U of M)	University of Washington and University of Massachusetts
	Specialized Active Network Technologies for Distributed Simulation (SANDS) (U of M)	University of Washington
		University of Massachusetts
Mobile code and safe languages	Critical Technologies for Universal Information Access	MIT
	Active Quality of Service	General Electric (GE Global Research)
Mobile code and safe languages	PLAN	University of Pennsylvania
	NetScript	Columbia University
	Liquid Software	University of Arizona

implementations were done in Java. At that time, there were concerns about deficiencies in the Java programming model regarding both security and resource consumption control as well as scheduling concerns, making resource constraint at the programming language level impossible.

The Extremely Reliable Operating System, EROS (Shapiro et al. 1997), recognized the fact that nodes are shared between users and that this unfortunately brings with it the fact that users have possibly conflicting or mutually adversarial desires. EROS began to wrestle with many of the active network operating system questions concerning resource control, security, and containment of faults, all while focusing on efficient network operation.

RCANE (Menage 1999) defines a resource-controlled framework for active network services. It is interoperable with PLAN (Pradhan and Chiueh 2000). RCANE supports resource reservations for network bandwidth, memory use, and computation, much like the NodeOS. The primary difference between RCANE and the NodeOS is NodeOS's flexible communication abstraction. RCANE allows only

link-layer communication, while the NodeOS allows any supported protocol to be used.

As the active network framework began to crystallize, new active operating systems were developed with the active network framework in mind. Bowman (Merugu et al. 2000), which runs on top of Solaris, was the first NodeOS developed by the active network community. Bowman implements a subset of the NodeOS interface and does not provide resource controls. SuezOS (Kohler et al. 2000), Click (Kohler et al. 2000), and Router Plugins (Decasper et al. 1998) allow various degrees of extensibility. Each system enables configuration of safe extensions into the kernel that can extend router functionality.

Scout, Janos, and AMP

Janos (Peterson et al. 2001) is a NodeOS built in the Scout operating system. It encapsulates the flow of input/output data through the system in an explicit path abstraction. Scout is thus able to implement both the

traditional and the active forwarding services using exactly the same mechanism. This makes it possible to integrate the NodeOS interface into a Scout-based router in a way that does not negatively impact the forwarding of nonactive packets.

The principal that creates a forwarding path must provide three pieces of information: (1) a sequence of modules that define how messages will be processed along the path; (2) a demultiplexing key, which identifies the packets that will be processed by the path; and (3) resource limits placed on the path, (e.g., how many packets can be buffered, the rate at which CPU cycles may be consumed, etc.). The NodeOS module is able to implement domain, channel, thread, and memory operations as simple wrappers around a Scout's path. More interestingly, a cut-through channel is simply implemented by a Scout forwarding path that does not pass through the NodeOS module, while in and out channels map onto a Scout path that includes the NodeOS module.

Active Network Node

The Active Network Node (ANN) (DeCasper 1999) seeks to balance the tension between the unprecedented network flexibility enabled by active networks and the efficiency of dedicated hardware that performs static processing, such as Application-Specific Integrated Circuits (ASICs). A single central CPU serving all ports is unable to keep up with link speed even for a small number of ports and relatively low bandwidth links (e.g., 10 Mbps). In ANN a general-purpose CPU and a Field Programmable Gate Array (FPGA) are used on every port of a switch backplane. This combination of CPU and FPGA is termed the "processing engine." The CPU takes care of the majority of active functions applied to a packet, while the FPGA implements performance-critical functions. Since both can be programmed on the fly, this approach seems to balance the tension between flexibility and speed.

As can be seen repeatedly in NodeOS architectures, there is an attempt at a tight coupling between the processing engine and the network. Also, as commonly occurs in active networks, the per-flow instance creation and management introduces a relatively high one-time overhead. Subsequent packets on the flow experience improved performance.

Active Network Hardware and Network Processors

Some researchers have suggested that at the level immediately below the active node operating system should lie network processors. The genesis of the network processor (NP) was driven by an increasing demand for high throughput combined with flexibility in packet routers. As a first step in the evolution to NPs, a switch fabric replaced the bus connecting network interface cards with the central control processor (CP). As demand for bandwidth grew, simple network interface cards were replaced by ASICs, which relieved the CP of many forwarding tasks. ASIC-based routers, however, were not flexible enough to meet the needs of the network equipment market.

Hardware development cycles tended to be too slow to accommodate the demand for new features and protocol support. The next step led the NP, namely the use of Application-Specific Instruction-Set Processors (ASIPs). These processors can be programmed relatively easily and quickly according to protocol and deployment needs.

Network processors (Kind 2002) implement a balance between hardware and software that helps to meet the demand for performance and programmability that active networks require. The topic of network processors is a large subject area in its own right, and space limitations require that a brief introduction be presented here. Application-specific integrated circuits have clear advantages in terms of performance; the hardware functions do not provide sufficient flexibility. In contrast, packet forwarding based on General Purpose Processors (GPPs) provides high flexibility, but FPGAs can be reprogrammed at the gate level, combining features from ASICs and GPPs. Unfortunately, high-level programmability of FPGAs still is very limited. NPs are specifically designed for fast and flexible packet handling. Typically based on an embedded processor with application-specific instructions and coprocessor support, NPs can achieve even packet processing at network interface speeds of several gigabits per second.

NPs have simpler arithmetic and caching units than GPPs; their speed is achieved through parallel packet processing in multiple execution threads. In addition, common packet-handling functions, such as tree look-up, classification, metering, policing, checksum computation, interrupt and timer handling, bit manipulation, and packet scheduling, are frequently supported by coprocessors or specific functional hardware units. Moreover, NPs are often teamed with an embedded GPP for more complex tasks. APIs provide an abstract view of the resources of the network node on an NP. The APIs are dedicated to different data-plane, control-plane, and management-plane services of the NP and can be used for developing portable network applications. APIs allow network-wide services to be implemented simply and quickly.

Active packets are typically small because of maximum transmission unit (MTU) limitations and are likely to be based on a simple instruction set. Execution of the packet is inherently conservative in its memory usage and as such can be implemented on NPs with limited memory. Within the NP, a packet would not be required to execute on a GPP, thus reducing the delay between arrival and program execution as well as full and quick access to router state.

It has been suggested that active code need not be inserted in active packets, but rather packets contain a pointer to existing code. This approach is useful when the active code is large and will need to be executed repeatedly. From an NP point of view, there are two options for the installation of the active code component. If the component contains a performance-critical code segment with the purpose of extending forwarding code, it has to be linked dynamically into the existing forwarding code on the NP. This may be in the form of either interpreted byte code for a preinstalled virtual machine or native core processor code. NPs provide mechanisms to direct non-performance-critical packets to the control processor

(e.g., using IP header options). Since active packets used for network management are generally less time-critical than user data, NPs can handle these intelligently.

NPs have been used to increase active network performance by just-in-time (JIT) compilation of active code. Although native NP code is extremely fast, Java byte code is convenient and flexible but slow. It has been shown that the Java byte code can be converted to NP code within the network, yielding performance gains. The time to compile the code (required only once) is on the order of the time it takes to interpret the code as Java does. Subsequent use of the same code would then be at the native NP speed. This can be coupled with code-caching techniques to further increase active network performance. For efficient JIT operation within the NP, the NP should have write access to the instruction memory and a sufficiently large instruction memory to hold the compiler and the JIT-compiled active code; currently not all NPs support these requirements.

ANALYSIS OF ACTIVE NETWORKS

Although there is a large body of results on architectural aspects of active networking, less research has been done on new forms of quantitative analyses of the unique aspects of active networking. One of these unique aspects is the tight integration between computation and communication networking.

Research at NIST (Carlinet et al. 2000; Galtier et al. 2000) has examined the computational aspect by seeking a uniform measure of CPU processing time for heterogeneous network architectures. The model consists of two parts: a node model and an application model. A semistochastic state-transition model represents CPU usage requirements of active applications. Active ping and multicast applications were shown to match analytical results. Three different scaling factors were proposed to transform a model accurate on one node into terms that prove accurate on another. Without this approach, crude techniques such as estimated time-to-live (TTL) values were assigned to each packet and then decreased at each hop or each time

a packet created another packet. Another crude approach has been to enforce an arbitrary limit on the CPU time that a packet can use at each node. Using an arbitrary limit ensures only a worst upper bound, and may also allocate less CPU time than an application requires.

Ultimately, the essence and fundamental uniqueness of active networking is the flexibility introduced by a tight integration of code and data within, and in service of, the communication network. As illustrated in Figure 14, both code and data flow within, and change the operation of, the network. Developers and researchers of legacy networks, comprised of inflexible and statically defined processing, have focused on improving the flow of data based on Shannon's fundamental insights into entropy and the bit, as well as analyses in support of moving bits, such as queuing theory (shown along the left side of the figure). With the tighter integration of code and data in an active network, a broader view of information encompassing both code and data in the form of Kolmogorov complexity (shown along the right side of the figure) is required. In this form of analysis, there is a focus on code and data as a combined entity (Bush 2002). Active packets in the Kolmogorov complexity framework may vary from static data, as in legacy networks, to pure executable code; as code, the packets act as small executable models of information.

Kolmogorov complexity is a measure of the descriptive complexity contained in an object. It refers to the minimum length of a program such that a universal computer can generate a specific data sequence. A good introduction to Kolmogorov complexity is contained in Ming and Vitanyi (1993). Kolmogorov complexity is related to Shannon entropy in that the expected value of $K(x)$ for a random sequence is approximately the entropy of the source distribution for the process generating the sequence. However, Kolmogorov complexity differs from entropy in that it relates to the specific string being considered rather than the source distribution. A challenge in applying Kolmogorov complexity is that it is not computable. Any program that produces a given string is an upper bound on the Kolmogorov complexity for this

Figure 14: Legacy versus active information frameworks

string; however, one cannot compute the lower bound. Estimates have been shown to be useful in providing information assurance and intrusion detection.

Because the word *active* in *active networks* refers to the ability to dynamically move code and modify execution of components deep within the network, this typically leads to the challenge of determining the optimal proportion of an active application that should be implemented as code versus data. A method for obtaining the answer to this question comes from application of the minimum description length (MDL) (Gao, Li, and Vitanyi 2000; Wallace and Dowe 1999). Let D_x be a binary string representing x . Let H_x be a hypothesis or model, in algorithmic form, that attempts to explain how x is formed. H_x is a predictor of x . MDL states that the sum of the length of the shortest encoding of a hypothesis about the model generating the string and the length of the shortest encoding of the string encoded by the hypothesis will estimate the Kolmogorov complexity of string x (Eq. 1).

$$K(x) = K(H_x) + K(D_x|H_x) \quad (1)$$

Note that error in the hypothesis (or model) must be compensated within the encoding. A small hypothesis with a large amount of error does not yield the smallest encoding, nor does an excessively large hypothesis with little or with no error. A method for determining $K(x)$ can be viewed as separating randomness from nonrandomness in x by “squeezing out” nonrandomness, which is computable, and representing the nonrandomness algorithmically. The random part of the string—that is, the part remaining after all pattern has been removed—represents pure randomness, unpredictability, or simply error. Thus, the goal is to minimize $l(H_e) + l(D_x|H_e) + l(E)$, where $l(x)$ is the length of string x , H_e is the estimated hypothesis used to encode the string (D_x), and E is the error in the hypothesis. The more accurately the hypothesis describes string x and the shorter the hypothesis, the shorter the encoding of the string.

A series of active packets carrying the same information are measured as shown in Figure 15. Choosing an optimal proportion of code and data minimizes the packet length. The goal is to learn how to optimize the combination of communication and computation

Figure 15: Trade-off between static data and algorithmic content and length as hypotheses vary for the same information

enabled by an active network. Clearly, if $K(x)$ is estimated to be high for the transfer of a piece of information, then the benefit of having code within an active packet is minimal. On the other hand, if the complexity estimate is low, then there is great potential benefit in including it in algorithmic form within the active packet. When this algorithmic information changes often and impacts low-level network devices, then active networking provides the best framework for implementing solutions (a specific example of separating nonrandomness from randomness, although not explicitly stated as such, can be found in predictive mobility management as discussed in Bush and Kulkarni [2001]). An active packet that has been reduced to the length of the best estimate of the Kolmogorov complexity of the information it transmits will be called the “minimum size active packet.” When the minimum size active packet is executed to regenerate string x , the $D_x|H_e$ portion of the packet predicts x using static data (E) to correct for inaccuracy in the estimated hypothesis.

In general, a wide range of programs, or algorithmic descriptions, can generate a bit-string. Often, it is the case that the size of a program, or with regard to the definition above, the algorithmic description, can be traded off for speed. Thus, we need to be careful to distinguish the above definition of complexity from space and time complexity. From the standpoint of bandwidth, we desire small size—namely, the descriptive complexity, which must be approximately equal to, or smaller than, the static data. However, from the standpoint of processing speed, faster, but possibly larger, code would be desired.

Consider the definition of conditional complexity (Eq. 2). In this case, the descriptive complexity of x is conditioned upon y . One can think of this as meaning that executing program p with input y generates x .

$$K_{\phi}(x|y) = \begin{cases} \min_{\phi(p,y)=x} (l(p)) \\ \infty, \text{ if there is no } p \text{ such that } \phi(p,y) = x \end{cases} \quad (2)$$

Conditional complexity is important because an active packet can contain both code and data, the proportion of which may vary. Consider p as the code in an active packet, y as static data in the packet, and x as the final “piece” of information represented by the packet. The function f could be considered the network processing (NodeOS/EE) upon which an active packet is executed.

SELECTED APPLICATIONS

In order to consolidate the material in this chapter, this section examines two applications that take advantage of the unique capabilities of active networks. The first is a proactive network management system called Atropos (Bush and Goel 2005) that views active packets as small models rather than data. The second is a network capable of automatically evolving network services as needed, using the extreme flexibility of the active network.

The Atropos architecture is designed to use benefits of active networking: the ability to use fine-grained executable models in the network to enhance communication. A virtual message is an active packet that carries state information anticipated to exist in the

future. A streptichron (from classical Greek meaning to “bend time”) is a virtual message in the form of an active packet facilitating prediction by carrying information in algorithmic form affecting a node’s notion of time. Fine-grained executable models, necessary to represent future behavior, carried by streptichrons are introduced in the form of active packets. The models are called “fine-grained” because they are intended to represent small portions in space and/or time. Executable code representing future behavior has the potential to be more compact than transmitting equivalent nonexecutable data in a piecemeal fashion. The justification for this can be found in the relationship among compression, prediction, and computation defined via Kolmogorov complexity as discussed in the previous section.

An Active Network Management System

Atropos provides a framework to accomplish fault prediction using a coupling of concepts from distributed simulation (Jefferson and Sowizral 1982) and active networking. Results collected from a single Atropos node for load prediction are shown in Figure 16. In today’s management systems, a management information base (MIB) maintains current state values. In Atropos, load is predicted as real-time (called “Wallclock”) advances. Thus, future as well as current values are available on the node. In Figure 16, the local virtual time (LVT) (future time), runs ahead of Wallclock time (current time). Predicted load values are refined until Wallclock reaches the LVT of a particular value. This data was collected using the simple network management protocol by polling an active execution environment that was enhanced with Atropos. Valleys occur between the sampled values in the surface plot shown in Figure 16 because no interpolation is attempted between samples.

A diagonal line on the LVT/Wallclock plane from the right corner to the left corner separates LVT in the past from LVT in the future; future LVT is toward the back of the graph, past LVT is in the front of the graph. Starting from the right-hand corner, examine slices of fixed Wallclock over LVT; this illustrates both the past values and the predicted value for that fixed Wallclock. As Wallclock progresses the system corrects for out-of-tolerance predictions. Thus, LVT values in the past relative to Wallclock are corrected. By examining a fixed LVT slice, the prediction accuracy can be determined from the graph. Consider a line defined by an LVT slice equal to a value of y LVT time units. Load values remain constant for all values of Wallclock equal to or greater than y time units. The final value, which remains invariant, is the actual value that occurred, while previous values were attempts to refine predictions.

Temporal Overlay

The goal of incorporating an optimistic parallel and discrete event simulation as part of network operation is to allow as much concurrent and parallel operation as possible within the network for projecting future events. Each node processes its portion of the simulation ahead of Wallclock time at the same time as other nodes. The Atropos framework enables an individual node to simulate its operation forward in time on multiple nodes. For simplicity, the simpler case of each node simulating its own future is presented. This can be logically viewed as a virtual overlay network running temporally ahead of the actual network. As shown in Figure 17, a virtual network modeling the actual network can be viewed as overlaying the actual network. The axis labeled “Space” represents the efficient use of large numbers of nodes, while the axis labeled “Time” represents the LVT of

Figure 16: Load-prediction application results on a single node

Figure 17: Temporal overlay (AN = active network node; L = logical process)

each node. The overlay shown above the actual system is sliding ahead of the actual system in time. A motivating factor for this approach is apparent when Atropos is viewed as a model-based predictive control technique in which the model resides inside the system to be controlled. The network environment is an inherently parallel one; using a technique that takes maximum advantage of parallelism enhances predictive capability.

The Magician (Kulkarni et al. 1998) execution environment is used in the implementation described in this work. Atropos messages are encapsulated inside Magician SmartPackets following the active network encapsulation protocol (Alexander et al. 1997) format. Several alternative active network architectures were considered before proceeding. At the time of our platform evaluation, Magician appeared to offer the most programming conveniences in terms of considering support for SmallState as resource control options that would ensure that active packets would not interfere among different users or applications as well as exceed per-node processing requirements. See Galtier (2001) and Bush and Goel (2005) for performance details.

Next, consider another active network application that takes advantage of the extreme flexibility provided by network code transported within packets. The active network differs from traditional architecture primarily in what it does not specify. In particular, it does not define how nodes work together to provide a network service; rather, it describes open programmable slots that must be instantiated to provide a particular network service. This is a new degree of freedom in network architectures speeding up network evolution.

A Self-Healing Communication Network

Fault-tolerant and self-healing systems should have the ability to self-compose solutions to faults. This should be an inherent part of system operation, rather than a structure imposed from “outside” the system. Genetic algorithms are on the path toward self-composing solutions; however, genetic algorithms as currently implemented require external control to manipulate the genetic material. In other words, the genetic algorithm itself must be programmed into the system. If the genetic algorithm code failed, then the self-healing capability would fail. Although this situation is not ideal, it is explored as a possible step toward a truly self-healing system.

Many active network components and services have been designed and implemented and are undergoing experimentation. The ABone (active network backbone) implements a relatively large scale (given the novelty of the technology) active network ($O(100)$ [Big-O notation; on the order of 100] nodes). However, the fundamental science required to understand and take full advantage of active networking is lagging behind the ability to engineer and build such networks. In fact, the current Internet, whose protocols were built on the ill-defined goal of simplicity, is only slowly being understood. An outcry from the Internet community, with its carefully crafted, static protocol processing, with massive documentation ($O(4000)$ Request for Comments) of passive (nonexecutable) packets is that the Internet is already “too” complex.

It is unlikely that an adaptive fault-tolerant system, no matter how resilient, would be accepted by industry or the community if it were considered “complex” in the colloquial sense. How can such systems, which require complexity to be adaptive, at the same time appear simple to understand and manage? Are active networks really more complex than the current Internet? Are adaptive applications built on active networks any more or less complex than the same applications built on the legacy Internet? Does a measure of complexity exist that would allow an objective comparison to be made? What are the benefits of an active network with respect to passive networks? Although these are extremely difficult questions to answer, this chapter attempts to lay the groundwork to answer them by proposing a complexity measure, Kolmogorov complexity, and proposing an adaptation mechanism, a genetic algorithm, based on an analogy with biological systems.

Descriptive complexity was applied to optimize the combined use of communication and computation within an active network to determine the optimal amount of code versus data. It was shown that if the Kolmogorov complexity of the information related to the prediction of the future state of the network is estimated to be high, then the ability to develop code, representing the non-random or algorithmic portion of that information, is low. This results in a low potential benefit for algorithmic coding of the information. The benefit of having code within an active packet would appear to be minimal in such cases.

Conversely, if the complexity estimate is low, then there is great potential benefit in representing information in

Figure 18: Active packet as DNA

algorithmic form within an active packet. It has been suggested (Bush 2002) that if the algorithmic portion of information changes often and impacts the operation of network devices, then active networking provides the best framework for implementing solutions. This is precisely the case in genetically programmed network services, a new class of services that are not predefined but that evolve themselves in response to the state of the network. In this chapter, we will restrict this class to the services that are programmatic solutions for perceived faults that occur in a network. Further research is required to generalize this class to include other types of network services.

Complexity and evolution are intimately linked. Kolmogorov complexity ($K(x)$) is the optimal compression of string x . This incomputable, yet fundamental, property of information has vast implications in a wide range of applications, including system management and optimization (Kulkarni and Bush 2000) and security (Bush and Evans 2001; Goel and Bush 2003). Active networks form an ideal environment in which to study the effects of trade-offs in algorithmic and static information representation, because an active packet is concerned with the efficient transport of both code and data. As noted in Figure 18, there is a striking similarity between an active packet and DNA. Both carry information having algorithmic and nonalgorithmic portions. The algorithmic portion of DNA has transcription-control elements as well as the codons (Bush 2003). The active packet has control code and may contain data as well. Kolmogorov complexity and genetic programming have complementary roles. Genetic programming has been used to estimate Kolmogorov complexity (Conte et al. 1997; De Falco et al. 2000). Genetic programming benefits from Kolmogorov

complexity as a measure and means of controlling not only the complexity, but also the size and generality of the result. One of the most obvious uses for complexity in networking is programmatic compression. In this chapter, the foundation is developed for using complexity to enable the network to self-heal.

A criticism of this approach might be that a genetically engineered protocol stack will create a complex framework that will be difficult to understand and maintain. However, our approach is to compose the framework from simple components. Each of these components will be individually verifiable with respect to its properties and actions. As the components are arbitrarily composed to form a protocol stack, some protocol stacks may be generated that violate the principles of safety, consistency, and correctness. One way to approach this is to define a fitness function that verifies the suitability of the stack with respect to the properties desired.

Genetic Algorithm for Service Composition

The Magician Active network (Bush and Kulkarni 2001; Kulkarni et al. 1998) is used to test the feasibility of the genetically programmed network service concept. An active packet representing the nucleus (assuming network nodes are like eukaryotes—cells containing nuclei) is injected into all the network nodes. The nucleus contains a population of chromosomes—strings of functional units. Operation of genetic network programming begins with injecting basic building blocks, known as “functional units,” into the network, as shown in Figure 19. Currently, this “genetic material” is flooded into each active node. However, the material will remain inactive in each active node until a fitness function is injected

Figure 19: Injection of nucleus and functional units at start-up

into the network. Receipt of a fitness function will cause evolution to proceed. Table 3 is a flowchart of the steps involved.

Functional units are very small pieces of code blocks that perform simple, well-defined operations on an active packet. Examples of functional units are Delay, Split, Join, Clone, and Forward. There is also a Null functional unit whose use is explained later. Chromosomes are strings of functional units as shown in Figure 20. Once a chromosome is assembled, the codons can be translated into amino acids at the ribosome. In other words, the string of functional units will operate on active packets from other applications (or other functional units) that traverse the node. The chromosome is represented in the code in a form similar to a Lisp symbolic expression, for example: *((Null Join Split) (Delay Split Join Delay))*.

Mutation and recombination occur among a population of genes. Mutation is a probabilistic change of a functional unit to another functional unit. Recombination is the exchange of chromosome sections from two different chromosomes. In Figure 20, a close-up of a single node can be seen containing a very short chromosome strand. A single incoming traffic stream, as shown in Figure 21, entering the center node is split into multiple streams. A different chromosome processes each stream. Note that currently in our implementation, the full traffic stream is split along each chromosome. However, it is hypothesized that traffic sampling could be used to reduce the overhead in creating the multiple streams.

Fitness functions can be designed to measure quality of service (QoS) at different layers of the traditional protocol stack. In this particular case, fitness measures are shown at the transport, network, and link layers. As a particular example, jitter control might have a fitness function that minimized per frame variance at the link layer. The network layer uses its capabilities to maximize successful packet reception probability, in other words, perform the function of routing packets. The transport layer would have a fitness function that attempts to minimize end-to-end packet variance. The key is that each of these

Table 3: Adaptive In-Line Genetic Communication Network Programming Algorithm

- 1) Inject functional units.
 - a. Propagate to all nodes.
- 2) Inject nucleus.
 - a. Propagate to all nodes.
- 3) Inject fitness function.
 - a. Propagate to all nodes.
 - b. Choose three functional units to form three independent chromosomes.
- 4) Clone "normal" packet traffic through each chromosome while simultaneously performing step 5.
- 5) Begin operation.
 - a. If mutation event is to occur:
 - i. Generate a random change in one of the functional units to another available functional unit.
 - b. If recombination event is to occur:
 - i. Select a cross-over point and swap portions of best parent chromosomes.
 - c. Otherwise, for each chromosome, select an available functional unit at random and append to each chromosome.
 - d. Compute fitness.
 - i. "Normal" packets flow through each chromosome.
 - ii. Compute a fitness value based on monitoring desired chromosome objectives, such as latency or jitter.
 - iii. Return fitness value to the nucleus.
 - e. Assign fitness to each chromosome.
 - f. Repeat from step 5a until a desired fitness threshold is reached.

Figure 20: Architecture of a single node

Figure 21: Breeding traffic streams

fitness functions must work together toward reaching the stated goal in a reasonable manner.

Recombination can occur both within a node and between two nodes. In addition, changing the route of a packet also effectively accomplishes a recombination because the packet processing will be dependent on the genetic material at each node traversed. A key component of the evolutionary process is the fitness function. Fitness functions are “user” defined and injected into the network to control the evolution of the genetic population. For example, in our initial tests, minimizing variance in transmission time was used as a simple fitness function. However, initial experiments quickly demonstrated that the design of the fitness function is the most critical element. It reminds one of the saying, “Be careful what you pray for . . . because you might get it.” Often the fitness was achieved, but in ways that were unexpected and sometimes detrimental to the intended operation of the network. As a trivial example, slowing the traffic to a near halt can minimize the variance. Thus, a low-latency term had to be added to the jitter control fitness function.

Although a priori techniques have been developed for jitter control in legacy networks, jitter control forms a simple, easily measured and controlled application for the network genetic algorithm. The functional units injected into the network should allow the evolution of a variety of interesting solutions to reduce variance, including adding delays and forwarding along different paths, or perhaps ideas that have not been thought of yet. An adaptive jitter-control mechanism was developed on a fixed, wired active communication network. The genetic algorithm was implemented as an active application in the Magician Active network execution environment. The dominant contributors to packet-link transit-time variability are the fact that the active network is an overlay network that has unspecified lower-layer traffic and that packets are loaded and executed within a Java Virtual Machine residing in each node and are subject to Java garbage collection, which runs at unspecified times.

The fitness function on all nodes returns a greater fitness when link transfer-time variance on the destination node is minimized. As previously mentioned, the fitness function is itself an active packet that consists of an objective function. The function is highly general and can be comprised of any mathematical function of accessible metrics. Bush (2003) shows packet-link transit-time variance through three of the chromosomes on the destination node and shows packet-link transit-time variance with no jitter-control mechanism at the destination node. Initial observation of the graphs shows that, overall, the chromosomes significantly reduced packet transit-time variance by a factor of 100. Another observation of the experimental data is that the genetically programmed transit-time variance was initially worse than transit-time variance with no control mechanism. The reason for this is that the chromosomes begin operation with a random set of functional units and require time to converge to an optimal value.

ACKNOWLEDGMENT

The work discussed in this chapter has been funded by the Defense Advanced Research Projects Agency (DARPA) contract F30602-01-C-0182 and managed by the Air Force Research Laboratory (AFRL) Information Directorate, under the auspices of the Fault Tolerant Networks program. Our thanks go to Doug Maughan, the Active Networks Program Manager, and Scott Shyne, Air Force Rome Labs (AFRL), for their generous support.

GLOSSARY

Active Application (AA): The execution environment on an active network device supports an active application. The active application consists of active packets that support a particular application.

Autoanaplasia: Autoanaplasia is the self-adjusting characteristic of streptichrons used in Atropos. One of the

virtues of the Atropos algorithm is the ability for the predictive system to adjust itself as it operates. This is accomplished in two ways. When real time reaches the time at which a predicted value had been cached, a comparison is made between the real value and the predicted value. If the values differ beyond a given tolerance, then the logical process rolls backward in time. Also, active packets, which implement virtual messages, adjust, or refine, their predicted values as they travel through the network.

Channel: An active network channel is a communications link upon which active packets are received. The channel determines the type of active packet and forwards the packet to the proper execution environment. Principals use anchored channels to send packets between the execution environment and the underlying communication substrate. Other channels are cut through, meaning that they forward packets through the active node—from an input device to an output device—without being intercepted and processed by an execution environment. Channels are in general full duplex, although a given principal might send or receive packets only on a particular channel.

Execution Environment (EE): The node operating system on an active device supports the execution environment. The execution environment receives active packets and executes any code associated with the active packet.

Node Operating System (NodeOS): The node operating system is the base level operating system for an active network device. The node operating system supports the execution environments.

Principal: The primary abstraction for accounting and security purposes is the principal. All resource allocation and security decisions are made on a per-principal basis. In other words, a principal is admitted to an active node once it has authenticated itself to the node, and it is allowed to request and use resources.

SmallState: SmallState is a named cache within an active network node's execution environment that allows active packets to store information. This allows packets to leave information behind for other packets to use.

INTRODUCTION

Future computer networks will be autonomous, scalable, adaptive, and robust. They will be autonomous and operate with minimal human intervention. They will scale and support billions of nodes and users. They will adapt to diverse user demands as well as dynamically changing network conditions. They will be robust and survive against network failures and attacks and remain available to users.

Key features of future computer networks mentioned above—that is, autonomy, scalability, adaptability, and robustness—have already been achieved in biological systems. For example, scalability is observed in large-scale social insect colonies (e.g., ant colonies) that contain millions of entities (e.g., worker ants), yet exhibit highly sophisticated and coordinated behaviors (e.g., division of labor in foraging and nest building). Insect colonies also adapt to dynamically changing conditions (e.g., change in the amount of food in the ant colony) through local interaction of entities that adjust their behavior based on conditions (e.g., more ants go out of a colony and gather food when the food level in the colony becomes low). Based on the observation that biological systems exhibit key features that future computer networks require, an increasing number of researchers are currently investigating the feasibility of applying biological concepts and principles to computer networks design.

The idea of drawing inspiration from biological systems exists not only in computer networks, but also in general computing. In biologically inspired computing, biological concepts and principles have been applied and resulted in new and widely accepted computing paradigms. Such biologically inspired computing may be divided into two types: in silico computing, in which biological concepts and mechanisms are implemented on computers to perform computation, and in vitro computing, in which physical properties of biological materials

are exploited to perform computation. In silico computing includes evolutionary computation (Mitchell 1998; Koza 1992), neural networks (Yao 1993), ant colony optimization (Dorigo, Di Caro, and Gambardella 1999), and amorphous computing (Abelson 2001). In vitro computing includes DNA computing (Adleman 1994) and cellular computing (Amos 2004). For an overview of biologically inspired computing, see, for instance, Castro and Von Zuben (2004).

This chapter is devoted to biologically inspired networking, applications of biological concepts to designs of computer networks. This chapter describes example biological systems and novel networking paradigm designs based on biological systems. The section on “Biologically Inspired Networking Paradigms” presents the key biological concepts and principles found in biological systems (e.g., nervous systems, immune systems, ant colonies, evolving systems, and cellular systems) and describes how inspiration is drawn from biological systems to create novel networking paradigms. It then provides examples of biologically inspired networking. The discussion section covers the current status and future directions of biologically inspired networking research.

BIOLOGICALLY INSPIRED NETWORKING PARADIGMS

This section presents new networking paradigms inspired by the observation of biological systems. The section consists of five subsections, each of which describes a different biological system: nervous systems, immune systems, ant colonies, evolving systems, and cellular systems. Each subsection first describes a biological system and highlights key biological principles and mechanisms, and then it describes how the key biological principles and mechanisms are applied to designs of computer networks.

Networking Paradigms Inspired by Nervous Systems

Nervous Systems

A nervous system is perhaps one of the most complex systems in nature. A human brain, for instance, involves billions of neurons, each interconnecting thousands of other neurons. Neurons running throughout a body, for instance, communicate to regulate and control various bodily functions.

A nervous system consists of the central nervous system (CNS) and the peripheral nervous system (PNS) (Figure 1). The CNS is composed of a brain and a spinal cord, and is responsible for processing information received from the PNS. The PNS is a network of neurons responsible for transmitting information between the CNS and the rest of a body (i.e., depicted as “Internal Environment” in Figure 1). The PNS is divided into the somatic nervous system and the autonomic nervous system. The somatic nervous system is responsible for controlling the body’s muscle movements and also for receiving stimuli from the external environment—that is, external stimuli. The autonomic nervous system is responsible for managing the internal environment of an organism (e.g., heartbeat, blood pressure), and also for receiving internal stimuli.

The autonomic nervous system has a feature of maintaining internal equilibrium of a body of an organism, called “homeostasis,” enabling the body of an organism to be highly robust against various environmental perturbations. The autonomic nervous system does so using negative feedback. For example, the autonomic nervous system of a homeothermic animal acts toward generating heat in response to low temperature (e.g., by causing shivering), while reducing heat production in response to high temperature (e.g., causing no shivering), and maintains body temperature at around 37°C. The autonomic nervous system regulates low-level details of body functions without requiring awareness or explicit control by an organism and maintains internal conditions within physiological ranges. By maintaining homeostasis, an organism can function more effectively. For instance, heterothermic animals tend to become sluggish at low temperatures, whereas homeothermic animals remain active.

Figure 1: The architecture of a nervous system

Autonomic Computing and Networking

Inspired by the autonomic nervous system, autonomic computing research was initiated by IBM (Kephart and Chess 2003; White et al. 2004), and is currently being carried out at a number of research institutions and universities. See IBM’s Web site (www.research.ibm.com/autonomic/research/projects.html) and published papers (Parashar and Hariri 2005; Hariri et al. 2006) for a list of autonomic computing research projects.

The main research challenge in autonomic computing is creating a computer system that self-configures, self-optimizes, self-heals, and self-protects in a manner the same as or similar to that of the autonomic nervous system. Analogous to autonomic nervous systems, an autonomic computing system is expected to operate without requiring external control and constant monitoring by human administrators. To fulfill those requirements, Parashar and Hariri (2005) proposed an architecture of autonomic computing based on the Ashby’s (1960) model, a model that explains the ability of an organism to maintain equilibrium through a nervous system.

Ashby first assumed that certain parameters of an organism (e.g., blood pressure) are more critical and are more closely linked to the survivability of the organism; he called such parameters “essential variables.” Ashby assumed that in order for an organism to survive, its essential variables must be kept within physiological ranges, and observed that many organisms undergo two types of disturbances: frequent and small impulses, and occasional and large stepwise changes. Based on this observation, Ashby proposed an architecture that consists of two key components: an environment and a reacting part, and contains two closed loops: one loop that reacts to frequent and small disturbances and another that reacts to occasional and large disturbances (Figure 2). The environment includes both types of environments described in Figure 1: the internal environment (or conditions) of an organism, and the external environment (or conditions) surrounding the organism. The reacting part represents a set of behaviors that the organism may trigger to maintain essential variables within physiological ranges. In the case of frequent and small disturbances, essential variables of an organism stay within physiological ranges, and an organism responds to the environmental disturbances by simply choosing an appropriate behavior from its existing behavior set. This response of an organism is called “primary feedback,” and is one way of maintaining homeostasis (or equilibrium with the environment). In the case of occasional and

Figure 2: Ashby’s model

large disturbances, its essential variables go out of physiological ranges, and an organism modifies the existing set of behaviors to adapt to the environmental disturbances. This is called “secondary feedback,” and is another way of maintaining homeostasis. In Ashby’s model, primary and secondary feedbacks are considered essential for an organism to maintain homeostasis.

Based on Ashby’s model, Parashar and Hariri (2005) designed autonomic elements, which are the smallest functional units in an autonomic computing system (Figure 3). As in Ashby’s model, an autonomic element contains two key components: an environment and a reacting part. The environment represents both internal and external factors impacting an autonomic element. The reacting part represents executable codes and data (or behaviors) of an autonomic element. Furthermore, inspired by Ashby’s model, Parashar and Hariri introduced two types of control loops between an autonomic element and its environment: local loops and global loops, corresponding respectively to primary feedbacks and secondary feedbacks in Ashby’s model. An autonomic element relies on a local loop to handle known situations based on local knowledge embedded in the autonomic element, and it relies on a global loop to handle unknown situations. For example, when a local system load exceeds a predetermined threshold value, an autonomic element invokes a local loop to apply the embedded local knowledge and control local resources to meet load-balancing requirements. On the other hand, when an autonomic element encounters unknown situations (e.g., when invoking a local loop fails to satisfy a requirement on load balancing), an autonomic element invokes a global loop to change existing behaviors; for instance, it invokes machine learning to introduce new knowledge.

The architecture shown in Figure 3 is an example of autonomic computing paradigms. Many other architectures for autonomic computing have also been proposed,

Figure 3: The architecture of autonomic elements

as listed on the IBM Web site (www.research.ibm.com/autonomic/research/projects.html). Although the idea of making computer systems fully autonomous and hiding all their complex and detailed operations from their human operators is still controversial, we believe that applying a nervous system model for computing system design has the potential to create efficient and stable computing systems.

Networking Paradigms Inspired by Immune Systems

Immune Systems

A natural immune system is a large-scale, complex, and adaptive system. It consists of multitudes of immune cells that interact through exchanging molecules within an organism. An immune system protects an organism against infections by pathogens such as bacteria, viruses, and parasites (Alberts et al. 2002). In vertebrates, there are two types of immune responses: innate immune responses and adaptive immune responses. Innate immune responses are the first line of defense and are carried out by particular types of immune cells. Innate immune responses are not specific to particular pathogens but can quickly respond by detecting molecules that are common to many pathogens and are absent in the organism. Adaptive immune responses are carried out by white blood cells, called “lymphocytes,” such as T cells and B cells, and are more specific to particular pathogens. Adaptive immune responses are slower but provide the ability to learn new infections.

The adaptive immune responses learn to fight new infection through trial and error. For example, T cells are created with randomly generated receptors, and within an organ called the thymus, T cells are trained not to bind to self but only to non-self. In the training process, T cells are exposed to self-proteins (i.e., proteins synthesized within the body of an organism). The T cells that bind strongly to self-proteins induce apoptosis (i.e., programmed cell death) and die, while others that do not bind to self-proteins are allowed to migrate in a body to detect foreign objects.

The ability to learn to fight new infection is enhanced through an adaptive process called “affinity maturation.” Affinity maturation is also achieved through trial and error. In affinity maturation, B cells with a higher affinity for a pathogen become activated with a higher probability, and clone themselves to proliferate. In order to increase affinity for pathogens, when B cells clone themselves, they mutate receptors at a high mutation rate (hypermutation), resulting in cloning of B cells with a slightly different affinity for pathogens. If the cloned B cells exhibit an even higher affinity than the parent B cell, the cloned B cells can be activated more easily and proliferate. Through the trial-and-error processes, an immune system achieves a high affinity for a particular pathogen. After a pathogen is eliminated, the lymphocytes with a high affinity for the particular pathogen become differentiated into long-lived memory lymphocytes that remain in the organism so that they can quickly respond if they encounter the same pathogen in the future.

Network Intrusion Detection

Natural immune systems, as described in the section “Immune Systems,” and computer networks share a common goal of protecting themselves against attacks and intrusion, and various concepts and mechanisms from natural immune systems have been implemented for intrusion detection of computer networks. Existing research that applies concepts and mechanisms from artificial immune systems includes an intrusion-detection system for wired networks (Kephart 1994; Forrest, Hofmeyr, and Somayaji 1997) and for wireless sensor networks (Bokareva, Bulusu, and Jha 2005). (For an extensive survey and the comparison of various models proposed in the literature, see Aickelin, Greensmith, and Twycross [2004].) The following provides a brief introduction to an architecture for artificial immune systems (ARTIS) proposed by Hofmeyr and Forrest (2000).

Analogous to natural immune systems, the ARTIS performs classification of self and non-self in an intrusion detection sense. Namely, given an arbitrary string representing a network activity (e.g., a network connection), the ARTIS performs classification of legitimate and illegitimate activities. In order to classify legitimate and illegitimate activities, the ARTIS uses mechanisms from natural immune systems, as described in the section on “Immune Systems.” For example, analogous to natural immune systems, which randomly generate receptors for pathogens, the ARTIS randomly generates detectors, each detector containing a randomly generated bit string, to recognize illegitimate activities. In the ARTIS, generated detectors are first exposed to the environment of self and non-self (i.e., legitimate and illegitimate network connections), represented as a set of bit strings (Figure 4). If a detector (i.e., a bit string of a detector) matches any bit string in the self-environment, the detector is eliminated. If it does not match or partially matches, it may become a mature detector and it is then released into the network to detect illegitimate activities.

A released matured detector is activated when similarity (e.g., Hamming distance) of the two bit strings representing the detector and a given network activity exceeds an activation threshold. An activated detector then performs a programmed action, such as notifying network administrators of possible illegitimate activities. When multiple detectors at a node are activated by the same non-self string, the detector with the closest match becomes a memory detector, analogous to affinity maturation of natural immune systems, in which lymphocytes with high affinity for pathogens become easily activated. In addition,

Figure 4: Generating detectors in ARTIS

the ARTIS relies on a mechanism called “memory-based detection” to remember past intrusion, inspired by the mechanism of natural immune systems to remember pathogens encountered in the past. In the ARTIS, memory detectors obtain a lower activation threshold than non-memory detectors so that they become activated easily in future responses. Memory detectors then clone themselves and spread to neighboring nodes.

The ARTIS and other artificial immune systems have successfully captured the essence of biological immune systems and achieved distributed intrusion detection for computer networks. Current artificial immune systems for computer networks are, however, simplistic and not fully autonomous, in the sense that human administrators need to make a decision about how to respond to detected illegitimate activities. One promising direction is to design more autonomous artificial immune systems that require minimal human intervention—for example, by incorporating necessary mechanisms of biological counterparts such as costimulation (a mechanism to reduce the chances of false-positive detection, thereby reducing human involvement) and other similar mechanisms (Hofmeyr and Forrest 2000).

Networking Paradigms Inspired by Ant Colonies

Ant Colonies

Social insects such as ants and bees form a large-scale and highly organized colony. Such an insect colony is decentralized, and there is no global coordination and communication among individual insects. In a large-scale insect colony, when individual insects with a set of very simple behavioral rules interact, intelligent group behaviors emerge from local interactions among individual insects. For example, an ant colony may contain millions of worker ants, yet through local interactions, it efficiently divides labor of nest repair, enlargement, and defense (Bourke and Franks 1995). Similarly, a bee colony that consists of thousands of honeybees coordinates through local interactions to efficiently collect nectar, pollen, and water (Seeley 1995).

The coordinated group behavior of social insects arising from local interactions, known as swarm intelligence, relies on two types of interactions among social insects: direct and indirect (Bonabeau, Dorigo, and Theraulaz 1999). Direct interactions are a straightforward mechanism, and allow insects to communicate through direct contact (e.g., by exchanging food and liquid). Indirect interactions are those in which some insects modify the environment and other nearby insects detect the environmental change and respond to it. This form of communication (i.e., indirect communication through the environment) is called “stigmergy,” and is observed in many of their intelligent group activities, including food foraging, nest building, and cemetery building. For example, in finding food sources, ants indirectly interact with each other by depositing and following a chemical substance called a “pheromone.” This simple mechanism of interactions leads to finding the shortest (or a shorter) path to a food source, as explained below. Consider a

situation in which ants randomly forage and find two different paths to a food source; one path being shorter than the other. Ants that take the shorter path can travel between the nest and the food source more often than the ants taking the longer path; thus, more pheromones are accumulated on the shorter path. Since a higher concentration of pheromones attracts more ants, the shorter path is further reinforced by many more ants, eventually leading most of the ants to follow the shorter path. (See the next section for more details.)

Network Routing

Inspired by the foraging behavior of ants, Dorigo et al. (1999) proposed ACO (ant colony optimization) as a solution to optimization problems in networks such as shortest-path-finding problems. Several routing mechanisms based on ant foraging behavior have also been proposed for the Internet (Di Caro and Dorigo 1998) and for mobile ad hoc networks (Gunes, Sorges, and Bouazzi 2002; Roth and Wicker 2003; Wedde et al. 2005). In addition, several frameworks to implement and evaluate various ant-based algorithms have been proposed (Montresor 2001; Montresor, Meling, and Babaoglu 2002; Bean and Costa 2005). The following briefly describes AntNet, a well-known routing mechanism based on ant foraging behavior, and Anthill, an application development framework for peer-to-peer networks.

AntNet is a routing mechanism for IP (Internet protocol) datagram networks inspired by the foraging behavior of social ants (Di Caro and Dorigo 1998). The particular metaphor taken from the observation of ant colonies is stigmergy (indirect communication through the environment). In AntNet, there are two types of ants, forward and backward ants, which interact indirectly by modifying a routing table of a networked node. This is analogous to real ants indirectly interacting by modifying the environment through pheromones. Each node of AntNet periodically launches a forward ant toward a probabilistically selected destination node to discover the best path to the node. Forward ants are initially routed according to a probabilistic routing table at each node, i.e., forward ants decide which node to go to next based on the probability

specified in the routing table of a node. While traveling toward a destination, a forward ant records the routing path it takes (i.e., a stack of nodes it visits) and the time it visits each node on the routing path. When a forward ant reaches a destination, it calculates the goodness of the path it just took (such as the total time required on the routing path to reach the destination node). It then creates a backward ant that carries information on the path and the path goodness. (The forward ant then dies.) A backward ant travels the path that the forward ant took in the opposite direction. While “backwarding” the path, a backward ant updates a routing table at each node, according to the goodness of the path, to lead more forward ants onto a better path (i.e., a path with better goodness value). This routing mechanism is analogous to ant foraging behavior, in which ants deposit pheromones on paths; shorter paths attract more ants, eventually leading to the shortest path (Figure 5). The performance of AntNet is compared against six other existing routing mechanisms, and is verified to result in higher throughputs and smaller packet delays.

In order to ease the implementation and evaluation of peer-to-peer applications, an application development framework for peer-to-peer networks—Anthill—has been proposed (Montresor 2001; Montresor et al. 2002). In Anthill, a network application is constructed by a network of peers called “nests.” A nest (i.e., a PC hosting Anthill) provides a storage space for documents and generates queries called “ants” (i.e., software agents) in response to a user’s request for a document. Ants travel over a network of nests in search of a requested document. During the search, ants indirectly interact with other ants by modifying the information that each nest maintains. For example, ants may leave a pheromone containing information regarding other documents and nests in order to facilitate the search processes of other ants. Anthill also supports evolution that allows some ants to mutate and exhibit different behaviors, which increases the variation and robustness of ant-based algorithms. Anthill provides a set of run-time libraries for development and monitoring to ease the implementation and evaluation of peer-to-peer applications.

Figure 5: Shortest path finding in AntNet

Ant-based mechanisms such as the ones described in this subsection are known to be useful for solving various complex problems, including the traveling salesman problem (Dorigo 1992), unicast and multicast routing (Guoying, Zemin, and Zheng 2000), and the clustering problem (Handl, Knowles, and Dorigo 2003). However, ant-based mechanisms are a variation of distributed learning algorithms, and thus, they require some time to obtain history and derive the optimal solutions. One key research issue in applying ant foraging behaviors is how to improve efficiency of the mechanisms.

Networking Paradigms Inspired by Evolving Systems

Evolution through Natural Selection

Biological systems evolve to adapt to and survive in a dynamically changing environment. Evolution in biological systems occurs as a result of natural selection from diverse behavioral characteristics of individual biological entities.

In the biological world, food (or energy) serves as a natural selection mechanism. Biological entities naturally strive to gain energy by seeking and consuming food. Biological entities that successfully obtain energy may reproduce more and survive longer than those that are not successful in obtaining energy.

In the biological world, diversity is maintained through various mechanisms such as mutation and crossover of genetic information (i.e., genes). When a biological entity (asexually) replicates, an offspring entity probabilistically undergoes mutation that modifies its genetic information. When two biological entities (sexually) reproduce, an offspring entity inherits a part of genetic information from a parent and the remaining genetic information from the other parent. Mutation and crossover of genetic information may allow an offspring to acquire behavioral characteristics that are different from those of a parent or parents, resulting in diverse behavior characteristics of individual biological entities.

Through natural selection of diverse biological entities over generations, beneficial features are retained, while detrimental behaviors become dormant or extinct, and the biological systems evolve to adapt to and survive in a dynamically changing environment.

Middleware Framework

Inspired by biological evolution through natural selection, Suda, Itao, and Matsuo (2005) and Wang and Suda (2001) proposed the Bio-Networking Architecture as a middleware framework for the design and development of network applications. The Bio-Networking Architecture supports the design and development of a wide range of applications, including content distribution services (Wang and Suda 2001) and dynamic service composition (Itao et al. 2004). In addition, the various aspects of the Bio-Networking Architecture have been empirically examined (Suzuki and Suda 2005) and investigated through simulation (Nakano and Suda 2005). The following explains how biological evolution is incorporated into the Bio-Networking Architecture.

In the Bio-Networking Architecture, network applications are implemented by a group of distributed, autonomous entities called the “cyber-entities” (analogous to a bee colony consisting of multiple bees). Each cyber-entity implements a functional component related to its service. It also follows simple behavior rules (such as migration, replication, reproduction, death, and energy exchange) similar to biological entities.

In the Bio-Networking Architecture, useful application functionality emerges from the collaborative execution of services carried by cyber-entities, and useful system behaviors and characteristics (e.g., self-organization, adaptation, scalability, and survivability) arise through the interaction of individual cyber-entities following simple behavior rules.

Within a biological system, diversity of behaviors is necessary for the system to adapt and evolve to suit a wide variety of environmental conditions. In the Bio-Networking Architecture, multiple cyber-entities are created to implement the same service but with different behavior policies (e.g., one cyber-entity with a migration policy of moving toward a user, and another cyber-entity with a migration policy of moving toward a node with a less expensive resource cost) to ensure a sufficient degree of behavioral diversity. In addition, the Bio-Networking Architecture creates and retains behavioral diversity among cyber-entities through mutation and crossover. Mutation may occur in replication and reproduction of cyber-entities, and it randomly modifies the genetic information that encodes behavior rules of offspring cyber-entities. Crossover may occur in reproduction, in which two parent cyber-entities create an offspring cyber-entity with mixed genetic information. Figure 6 illustrates crossover and mutation in a reproduction process, where genetic information of a cyber-entity encodes its behavior (e.g., migration behavior) as a set of weights (i.e., a series of rectangles in Figure 6, where each rectangle represents a weight). As shown in Figure 6, crossover randomly takes a weight from either parent (parent A or B) to create a new set of weights, and then mutation randomly changes some weights. An offspring entity that acquires the resulting set of weights may behave differently from either of the parents.

Within a biological system, food (or energy) serves as a natural selection mechanism. Similar to a biological entity, each cyber-entity in the Bio-Networking Architecture stores and expends energy for living (Figure 7). Cyber-entities gain energy in exchange for performing

Figure 6: Crossover and mutation

Figure 7: Energy acquisition and consumption as a natural selection mechanism

a service for other cyber-entities, and they pay energy to use network and computing resources on the Bio-Networking Platform (i.e., an execution environment of cyber-entities). The abundance or scarcity of stored energy affects various behaviors of cyber-entities and contributes to the natural selection process in evolution. For example, an abundance of stored energy is an indication of high demand for the cyber-entity; thus, the cyber-entity may reproduce often. A scarcity of stored energy (an indication of lack of demand or ineffective behaviors) may eventually cause the cyber-entity to die out.

Reproduction and replication create a population of cyber-entities with diverse behaviors. Through natural selection, fitter cyber-entities accumulate energy and proliferate, while others exhaust energy and die. Cyber-entities are able to adapt in this manner to the environment as well as to environmental changes.

Biologically inspired evolution mechanisms designed for the Bio-Networking Architecture relies on random processes (i.e., mutation), and thus, it may require significant time to achieve desired application performance (e.g., low latency in content delivery). In addition, there is no guarantee that a network application achieves optimal performance. Evolution may not even improve but rather degrade performance because evolution has to go through a large number of generations, consuming network and computing resources. Because evolution takes time and requires resources, applying the concept of evolution may not be viable in implementing applications for highly dynamic networks and applications for limited computing and networking resources.

Networking Paradigms Inspired by Cellular Systems

Cellular Systems

A multicellular organism starts with a single cell (i.e., a fertilized egg) and successfully develops into complex structures, such as tissues and organs. In the developmental process of multicellular organisms, gene expression in a cell controls the following four essential cellular behaviors: proliferation, specialization, interactions, and movement. Cell proliferation produces cells through cell division. Cell specialization creates cells with different characteristics at different positions. Cell interactions allow cells to coordinate with nearby cells, for example,

through the use of diffusive signal molecules. Cell movement rearranges the cells to form structured tissues and organs. In developmental processes, cells express a particular set of genes to trigger these four essential cellular behaviors to form a complex multicellular structure.

The development process of multicellular organisms typically progresses massively in parallel without central control (Alberts et al. 2002). For example, consider the development process of an embryo. Although all cells within a developing embryo contain identical genetic information, cells develop into different parts of an organism by expressing different sets of genes based on the internal and external environmental conditions of a cell. Different sets of genes are expressed in different cells of a developing embryo. Which set of genes to express in a cell depends on the environmental conditions (e.g., concentration gradients of signal molecules such as morphogens) of the cell and is not controlled by a central entity. Cells share the common set of genes, yet they are able to form a complex multicellular structure with precision.

Application Development Framework

Cellular systems have inspired networking paradigms. For example, cell-based programming is an application development framework that is inspired by the developmental process of multicellular organisms (George, Evans, and Marchette 2002). *Design patterns from biology* is a conceptual framework to design network applications inspired by the common cellular behaviors and processes such as interactions through the use of diffusive signal molecules (Babaoglu et al. 2005). Other examples include attempts to apply cellular signaling mechanisms to the design of autonomous and scalable communication systems (Krüger and Dressler 2004; Dressler 2005). The following introduces one of the above-mentioned networking paradigms—cell-based programming and its application to computer networks.

Cell-based programming is an application development framework based on developmental processes of multicellular organisms (George et al. 2002). Analogous to a multicellular organism, an application in the cell-based programming paradigm is created by a group of artificial cells. Every artificial cell of an application contains a set of identical behavior rules, corresponding to DNA of a biological counterpart. Each artificial cell follows a set of behavior rules (i.e., cell proliferation and specialization described above). For example, cells proliferate through cell division and become specialized when placed at different positions. Cells emit artificial signal molecules into the environment, and the emitted signal molecules diffuse according to the environmental conditions such as concentrations of signal molecules. Cells may die when environmental conditions change. Although all artificial cells contain an identical set of behavior rules, it is possible to form a complex structure by activating a different subset of the behavior rule set as reactions to different environmental conditions and by cascading cellular reactions (e.g., by making a local reaction lead to another interaction). This is analogous to a multicellular organism, in which constituting cells express different sets of genes and become specialized to form a multicellular structure.

Figure 8: Interactions between artificial cells in cell-based programming

Figure 9: File distribution based on cell-based programming

Figure 8 illustrates local interactions among cells. Assume that artificial cell A that is diffusing signals dies. After artificial cell A dies, artificial cells B and C detect that the signal concentration around them decreases, alter their states, and become specialized into B' and C'.

Applications developed using cell-based programming are highly fault-tolerant and exhibit a self-healing property, since an assembled cellular structure in cell-based programming can recover from damage (e.g., loss of a group of cells) through cell division and coordination (e.g., signal diffusion) without using global knowledge and communications. It is important to note that a robust structure may be formed from unreliable and fragile cells following a simple set of behavior rules.

George et al. (2002) has applied the cell-based programming paradigm to the design of a peer-to-peer file-sharing service for mobile wireless networks. The goal of the application is to reliably distribute files over a network of unreliable nodes (e.g., unreliable cells). In the application, when a node publishes a file, it broadcasts two types of signals: replicate and inhibit (Figure 9). Replicate signals propagate over a larger area than inhibit signals. A node that receives replicate signals but does not receive inhibit signals (i.e., shaded nodes in Figure 9) makes a copy of the file, stores that copy, and further diffuses inhibit and replicate signals for the file it copied. In this manner, a certain distribution of files (e.g., a certain structure of cells) is created. Analogous to a robust biological cellular structure, the file distribution generated in this manner without central control and global knowledge is highly robust against node failures and exhibits a self-healing property.

As seen in cell-based programming, current approaches mimic only macroscopic cellular behaviors

and may be too simplistic. Further study is necessary to analyze dynamic behaviors and complex properties of cells in biological systems, and to incorporate them into a design of computer networks. We believe that applying dynamic behaviors and complex properties of cells allows the emergence of robust structures with highly functional components in computer networks, as evident in biological systems.

CONCLUSION

Biological systems present fascinating features such as scalability and adaptability; thus, they have inspired new networking paradigms. Specific inspiration or model systems used in literature, as in this chapter, include autonomic nervous systems, immune systems, insect colonies (ant colonies), evolving systems, and cellular systems. The feasibility of applying biological concepts and mechanisms to computer networks has been extensively investigated through various simulation studies. Some of the simulation studies used data from real networks and confirmed the improved performance over existing approaches (see, for example, Di Caro and Dorigo 1998 and Hofmeyr and Forrest 2000). In addition, various bio-inspired experimental systems have been developed and are available for empirical investigation and application development (e.g., Montresor 2001 and Suzuki 2005).

Future work in biologically inspired networking includes exploring molecular and cell biology, and identifying new design principles applicable to computer networks. Some areas worth exploring in molecular and cell biology include signal transduction (e.g., biochemical reactions within a cell or across a cell membrane that results in cascading reactions, leading to various cellular processes), gene regulatory networks (e.g., networks of messenger RNA, which regulate DNA transcription or gene expression), oscillatory processes (e.g., cyclic behavior such as circadian clocks that enable a cell to adapt to a day-and-night cycle), and cell-cycle regulation (e.g., mechanisms to correct errors in cell cycles and to regulate metabolic activities). Such biological systems may be viewed as distributed information-processing systems, and some of the design principles found in such biological systems may be applicable to computer network designs.

Future work also includes establishment of a unified framework based on common mechanisms found across different biological systems. Such an abstracted framework may serve as a generic model and provide general design principles for computer networks. Some of the important design principles found in biological systems may include the following:

- *A large number of redundant components.* A biological system is composed of a large number of redundant components, as seen in all five biological systems described in this chapter. A nervous system may contain billions of neurons, and an ant colony may contain a million of ants. Because of the large number of redundant components, a biological system is robust in the event of failures and misbehaviors of a small number of components.

- **Local interactions and collective behavior.** Useful group properties and behaviors often emerge from local interaction of individuals with a simple set of behavioral rules. For example, although individual immune cells may sometimes erroneously identify foreign objects, an immune system (i.e., collection of interacting immune cells) as a whole reliably detects and eliminates foreign objects. This is a result of individual immune cells interacting and coordinating to minimize the impact of errors caused by individual immune cells. Similarly, although individual ants are not able to find the shortest path to a food source, a group of ants as a whole finds the shortest path as a result of individual ants interacting through pheromones.
- **Stochastic or probabilistic nature.** The stochastic nature of biological systems often contributes to exploring search space. For example, ants do not always follow the already-found shortest path; rather, they probabilistically choose different paths to seek possible shorter paths. The stochastic nature also contributes to increasing diversity, thereby improving adaptability to the environment. In genetic evolution, for example, mutation randomly alters genetic information, which may create fitter organisms, enabling a population of individuals to become more adapted to the environment.
- **Feedbacks.** Biological systems often use two types of feedbacks: negative feedback to reduce the effect of environmental noise, and positive feedback to amplify signals in the environment. For example, in homeostatic biological systems, negative feedbacks are used to maintain an organism's essential variables within physiological ranges, providing the organism with stability and robustness against environmental perturbations. In ant foraging, on the other hand, ants use positive feedbacks to amplify signals (i.e., pheromones) and to recruit more ants toward a particular path; that is, ants follow a path with higher pheromone concentrations, resulting in further enhancement of the pheromone concentration of the path.

In addition to identifying important design principles by analyzing various biological systems, it is also important to establish metrics to evaluate key system properties such as autonomy, scalability, adaptability, and robustness. Such evaluation metrics would help in evaluating and comparing computer networks modeled after various biological concepts and mechanisms.

GLOSSARY

Autonomic Nervous System: A part of peripheral nervous system that is responsible for managing the internal environment of an organism and receiving internal stimuli.

B Cells: Lymphocytes that produce antibodies.

Central Nervous System (CNS): A part of the nervous system that consists of the brain and the spinal cord.

Crossover: The process by which two chromosomes exchange some distal portion of their genes.

Hamming Distance: The number of positions for which the corresponding symbols are different.

Homeostasis: Internal equilibrium of a body of an organism.

Mutation: Change of gene caused by copying errors in the genetic material during cell division.

Peripheral nervous system (PNS): Nerves and neurons that reside or extend outside the central nervous system (CNS).

Somatic Nervous System: A part of peripheral nervous system that is responsible for controlling the body's muscle movements and receiving stimuli from the external environment.

Stigmergy: A method of communication in emergent systems in which the individual parts of the system communicate with one another by modifying their local environment.

Swarm Intelligence: An artificial intelligence technique based on collective behavior in which simple agents interacting locally with one another and with their environment lead to the emergence of global behavior.

T Cells: Lymphocytes with receptors responsible for recognizing antigens.

INTRODUCTION

The prefix nano means 1/1,000,000,000 or simply a billionth. Nanotechnology deals with structures or devices that are 100 nm or less in size (the diameter of a human hair is roughly 50 μm and the smallest thing visible to the human eye is around 10 μm). Nanotechnology has applications in virtually all disciplines, including electronics and optics. It promises to revolutionize computers, communications, and interdisciplinary sciences. Every communication system has three basic building blocks: the signal source, communication media, and signal detector. A subset of components, such as signal modulators, filters, amplifiers, switches, routers, and encryption devices complement these basic blocks. Current state of the art in nanotechnology offers a wide range of devices that encompass most aspects of communications system. These devices are gradually transitioning out of the research environment and are slowly maturing into commercial products. The vertical-cavity surface-emitting laser (VCSEL) is an example of a commercially available nanoscale signal source that has replaced conventional laser diodes in many applications. Similarly, photonic crystals are finding a multitude of applications in optical communication media such as optical waveguides, planar waveguides, fibers, and filters. Quantum cryptography is an encryption scheme that is nearly impossible to crack. This technique generally relies on single-photon devices. Quantum dots are used to build devices such as single-photon sources and detectors.

Quantum dots can also be used as sources and generators of entangled electron pairs. Carbon nanotubes exhibit remarkable electrical properties, with many applications in all the three basic communication blocks. Similarly, MEMS and NEMS (microelectromechanical and nanoelectromechanical systems) are used in a wide variety of nanoscale devices for switching and routing applications (www.allaboutmems.com/memsapplications.html). A host of chemical dendrimers, that include monomers and polymers, are increasingly used in optical amplifiers like erbium-doped fiber amplifier (EDFAs) to enhance efficiency. In addition, various nanodevices such as transistors, Mach-Zehnder modulators, and terahertz lasers are also available for communication-related applications. Silicon photonics and surface plasmons are both relatively new areas of focus in nanotechnology. Their applications to nanoscale communication are discussed in this chapter. Some devices presented in this chapter may fall outside the 100-nm range, but these devices are often referred to as nanodevices in the literature and there is a continuous effort to scale down these larger devices to the nanorange (Poole and Owens 2003; Ratner and Ratner 2002).

VERTICAL-CAVITY SURFACE-EMITTING LASER

A vertical-cavity surface-emitting laser (VCSEL) is one of the smallest commercially available laser sources.

Figure 1: Typical VCSEL structure (adapted from www.atvoigt.de/modules/EZCMS/pictures/VCSEL.jpg)

Up to 20,000 VCSELs can be packed on a 3-in. wafer (ICielo Communications). A regular laser diode consists of multiple semiconductor layers and emits its infrared energy parallel to these layers. A VCSEL, on the other hand, emits its infrared energy perpendicular to these layers. As shown in Figure 1, the resonant cavity consists of two distributed Bragg reflector mirrors parallel to the wafer surface with an active region consisting of one or more quantum wells for generation of laser energy between them. The planar distributed Bragg reflector mirrors consist of layers with alternating high and low refractive indices. Typical VCSEL junction diodes have their upper and lower mirrors doped as p-type and n-type, respectively, while materials used for manufacture include gallium arsenide (GaAs), aluminum gallium arsenide (AlGaAs), and indium gallium arsenide nitride (InGaAsN). A VCSEL manufactured with GaAs/AlGaAs usually emits in the 850-nm wavelength range. To achieve different wavelengths, different materials are used. VCSELs have extremely short cavity lengths, usually only a few microns long, which allows single-frequency operation as well as some wavelength tunability. VCSELs can operate up to 10 Gbps. They have many advantages, including low power consumption, high transmission speeds, relatively low manufacturing cost, high reliability, and high efficiency. The room-temperature operation of VCSELs eliminates the use of extensive cooling systems. VCSELs have low manufacturing cost, as surface emission allows testing at the wafer level, before individual VCSELs are packaged. The circular and low divergence output beam of VCSELs eliminates the need for corrective optics. VCSELs are commercially available as single-mode and multimode devices, both of which can operate in the gigabit region (www.lightreading.com/document.asp?doc_id=2580&page_number=3; Verdeyen 1995). Surface plasmon-based VCSELs are actively being investigated as low-power and high-data-rate laser devices. Such VCSELs will be discussed in the later sections of this chapter.

PHOTONIC CRYSTALS

Photonic crystals are multidimensional periodic dielectric nanostructures that are designed to control and manipulate the propagation of electromagnetic waves. A major source of noise in lasing systems is spontaneous emission. Photonic crystals tend to inhibit spontaneous emission by eliminating certain electromagnetic modes; they do this by modifying the radiative field coupling. This significantly reduces the threshold current and noise in semiconductor lasers (Joannopoulos, Meade, and Winn 1995; Johnson and Joannopoulos 2002).

Optical Waveguides

Photonic crystals can also be used as optical waveguides. Conventional optical waveguides rely on total internal reflection and yield acceptable results only in cases in which the bending radius of the waveguide is larger than the wavelength of the light. This scenario is not practical if we want to scale down optical equipment to the nano-scale. In such situations, most of the light will be lost at the bend. Photonic crystal waveguides rely on photonic band gaps to propagate light. The crystal is fashioned in such a way that the light is allowed to propagate only along specific paths, as depicted by the arrow in Figure 2. This allows sharp bends with no light loss. On the whole, photonic crystal waveguides offer virtually no absorption and are perfect mirrors as compared with conventional waveguides (Fan et al. 2001; Johnson et al. 2000).

Filters

Photonic crystals can also be used to make filters. As previously mentioned, a photonic crystal can manipulate and control the propagation of electromagnetic waves, depending on its structure. The nanostructures

Figure 2: Photonic crystal optical waveguide

can be arranged in a fashion that allows only certain wavelengths to travel through the material, and filters out others. Such filters are more efficient, less bulky, and more accurate than conventional filters. Photonic crystal filters are important devices in nanoscale optical communication. Polarizing filters can also be made using the birefringence property of photonic crystals (Solli and Hickmann 2004).

Planar Antennas

Planar antenna substrate is another application of photonic crystals. The efficiency of a conventional planar antenna is approximately less than 50 percent because half of the energy of the propagating wave is absorbed by the semiconductor substrate. One way to overcome this problem is to design the substrate in such a fashion that it acts as a mirror reflecting back the energy of the electromagnetic wave toward the antenna surface. A photonic crystal can be used to make this type of reflecting surface, as illustrated in Figure 3. This modification renders planar antennas more efficient, along with the added benefit of size reduction. Planar antennas are very important in monolithic millimeter-wave integrated circuits (MMICs). MMICs are increasingly used in satellite systems, in which smaller circuits are needed. MMICs are also useful in systems for which the parasitic reactance, inherent in hybrid integrated circuits, degrades the circuit performance, especially in the upper microwave and millimeter-wave spectrum. Communication devices and systems such as phased-array antennas and high-frequency radars rely heavily on MMICs. The use of photonic crystals in these circuits greatly improves the overall efficiency of the system (Brown, McMahon, and Parker 1998; Brown, Parker, and Yablonovitch 1993).

Fibers

Photonic crystals can be used to make optical fibers. These fibers are also called “holey fibers,” “hole-assisted fibers,” or “microstructure fibers.” Unlike other photonic crystal devices that derive their properties from periodic spatial arrangements, the photonic crystal fiber (PCF) owes its waveguide properties to an arrangement of tiny air holes that run through the entire length of the fiber, as illustrated in Figure 4. Different arrangements of air holes yield different properties. These fibers have relatively high numerical aperture (0.6 or 0.7) and offer single-mode guidance over a large range of wavelengths; they exhibit low sensitivity to bend losses, even for large mode areas. They can be manufactured to offer the possibility of a fundamental mode cut-off, allowing the design of single-polarization

Figure 4: PCF fiber (notice air holes)

fibers and the suppression of Raman scattering. In short, photonic crystal fibers are used for many applications, including amplifiers, nonlinear devices (frequency combs, Raman conversion or pulse compression), and quantum optics (www.crystal-fibre.com/support/dictionary.shtml; www.rp-photonics.com/photonic_crystal_fibers.html; Bjarklev, Broeng, and Bjarklev 2003; Russell 2003).

Photonic crystals are used to build a number of optical communication components, whose properties are far superior to traditional devices. These components can also be used to manufacture photonic integrated circuits—circuits using photons instead of electrons in semiconductor integrated circuits. The photon-only system is optimal for optical communications and will greatly boost transmission capabilities.

QUANTUM COMPUTING

Quantum computing uses certain quantum mechanical properties, such as superposition and entanglement, for computations. Unlike conventional computers that use binary bits, quantum computers use quantum bits (also known as qubits). Superposition occurs when a particle simultaneously possesses two or more values for a measurable quantity, such as energy. Quantum entanglement occurs when the quantum states of two particles have to

Figure 3: Radiation being absorbed by semiconductor substrate (left) and reflected by photonic crystal (right)

be described with reference to each other, even if they are spatially separated. A qubit differs from a binary bit in the sense that it is not binary but quaternary in nature. It can exist in the state 0 or 1 or simultaneously at both 0 and 1, with a probability for each state. The blend of states 0 and 1 is termed *superposition*. The details of the operation of a quantum computer are beyond the scope of this chapter. This paragraph serves as an introduction to discuss some communication systems based on quantum mechanics (www.cs.caltech.edu/~westside/quantum-intro.html; www.trnmag.com/Stories/2005/121905/HiW_Quantum_computing_121905.html).

Quantum Cryptography

Traditional cryptography relies on mathematical equations to encrypt information that restricts eavesdroppers from learning the contents of the message. Although the methods used nowadays are very reliable, there is always a probability that an eavesdropper can decrypt the message. Quantum cryptography promises to eliminate eavesdropping completely. It uses the physical properties of photons or electrons to encrypt the information. In order to decrypt the message, the eavesdropper has to measure the quantum carrier of information (usually the photon or the electron, though other entities are also used); however, doing so disturbs the system. This disturbance is recognized as a security breach, thus terminating the secure connection. This technology is reasonably mature, and many commercial products are available. ID Quantique and MagicQ are some commercial entities that provide various devices for quantum cryptography such as quantum key distributors, quantum random number generators, and quantum encryptors.

SINGLE-PHOTON DEVICES

Photons are often used as information carriers. Encoding information into these photons as qubits requires novel devices capable of emitting and detecting a single photon. A conventional optical communications network requires the signal to be above a certain threshold. In contrast, a qubit decoding system has to be able to detect each individual photon that has been transmitted, as each photon contains vital information. The same principle applies to the encoding process as well.

A single-photon source must possess some of the following basic properties, among others. It must be capable of generating the photons one by one, it must be efficient, it must allow polarization control, and it must allow photon generation on demand. Examples of such devices include single-photon light-emitting diodes (LEDs), quantum dots and some lasers with attenuators. On the other hand, a single-photon detector must have very high quantum efficiency, approaching 100 percent. Quantum efficiency of a detector can be defined as the ratio of the number of output quanta to the number of input quanta. It must have a low dark count rate, ensuring elimination of false count and afterpulsing. In addition, it must have a fast operating speed and must be able to resolve the amount of energy or the number of photons. Avalanche photodiodes, photomultiplier tubes, quantum dots, and superconducting

single-photon detectors are just a few devices that can be used as photon counters. Upconversion (the process by which a low-energy photon is converted to a high-energy photon) is a popular method of counting photons.

QUANTUM DOTS

A quantum dot is a semiconductor crystal measuring between 2 nm and 10 nm in diameter. Simply stated, a quantum dot is a structure whose size has been reduced to the quantum scale in all three dimensions. Quantum dots can be differentiated with quantum wires which have their sizes reduced to the quantum scale in only two dimensions, and size reduction in quantum wells, is one dimension only. Discussed below are some nanoscale devices that can be modeled after the quantum dot.

Quantum-Dot Laser

The quantum-dot laser is a relatively new development in the field of nanoscale communications. It is based on quantum dots, which are densely packed in the active region of the device. The quantum dots are excited into a high-energy state and the transitions to the lower-energy states release energy in the form of photons. Exciting an array of quantum dots thus creates lasing. The major advantage of a quantum-dot laser over its semiconductor counterpart is its ability to maintain constant output despite temperature fluctuations. The structure of quantum dots causes electrons to show a discrete atomic-like energy spectrum. The energy difference between these discrete states is greater than the thermal energy available to the electrons because of the size of the quantum dot (Klimov 2003). Thus, the quantum-dot laser is temperature-insensitive. Fujitsu and the University of Tokyo have successfully developed a 10-Gbps quantum-dot laser operating at a wavelength of 1.3 μm . This laser is immune to variations in temperature between 20°C and 70°C (www.fujitsu.com/global/news/pr/archives/month/2006/20060420-01.html; www.fujitsu.com/global/news/pr/archives/month/2004/20040910-01.html; www.fujitsu.com/news/pr/archives/month/2004/20040910-01.html; Phillips et al. 1999).

Single-Photon Source

Quantum dots can also be used to manufacture single-photon sources. Such devices are necessary for quantum communication. Quantum dots can be excited to emit light of a unique wavelength. The wavelength of the emitted light depends on the dot size. NIST (National Institute of Standards and Technology) has used an infrared laser to excite a quantum dot, leading to serial emission of photons. However, this behavior is achievable only at extremely low temperatures, approaching absolute zero. Another single-photon LED based on the quantum dot was developed by Toshiba (Ward et al. 2005). The LED uses a single quantum dot to produce the photon. Because the quantum dot is a single quantum system, it can hold only one electron in a particular excited energy level. Whenever the electron relaxes to a lower energy level, it

releases one photon. Thus, every time the quantum dot is excited, it releases one photon. Using voltage pulses, a stream of photons can be created. Typical materials used to manufacture the LED are gallium arsenide and indium arsenide. Indium arsenide is generally used for the quantum dot (Farahani et al. 2005; Ikushima et al. 2005; Shields et al. 2001).

Single-Photon Detector

Quantum dots have been successfully used as single-photon detectors. A quantum dot is encased in a resonant diode that has an insulating aluminum arsenide layer sandwiched between two conducting gallium arsenide layers. As a result the resonant diode is modified in a fashion that allows the diode to turn on when the quantum dot is excited by an incoming electron. In general, the diode is on when the two gallium arsenide layers have the correct voltage polarity. This device can find applications in quantum communication.

Another type of quantum-dot single-photon detector has been developed by Toshiba (Shields et al. 2001). The device is based on a transistor structure. The conducting channel of the transistor consists of a layer of closely spaced quantum dots. Since the separation of the quantum-dot layer and the conducting channel is on the order of a few nanometers, the resistance of the transistor is dependent on the change in the occupancy of a single quantum dot by a single electron. Hence, when photons are absorbed, a change in the resistance of the transistor channel occurs. This type of photon detector has many advantages over conventional photon detectors based on the avalanche process. The conventional photon detectors are relatively bulky, inefficient, expensive, require cooling systems and often require high voltages (Farahani et al. 2005; Ikushima et al. 2005; Ward et al. 2005).

Entangled Photon Pairs

Entangled photon pairs consist of photons that are inextricably linked. The state of each photon can be deduced by measuring the other, irrespective of the distance between the photons. Entanglement enables secure communication by detecting instances of eavesdropping. Consider the case of an encrypted connection. Encryption keys have to be exchanged between the two parties. If one of the keys is intercepted by an external agent, the properties of the entangled pair will change, and both parties should be able to detect it. As a result, entanglement leads to virtually unbreakable encryption. Such a quantum-dot device (developed by Toshiba and Cambridge University in 2005) is made from gallium arsenide and indium arsenide quantum dots. When excited by a laser pulse, this device produces two entangled photons. However, this behavior is currently limited to low temperatures.

CARBON NANOTUBES

Nanotubes are members of the fullerene structural family. A nanotube is basically a graphene sheet that has been rolled up into a cylindrical shape with at least one of the ends closed off by a semi-buckyball structure, as shown in

Figure 5: Carbon nanotube structure (adapted from www.nanomedicine.com/NMI/Figures/2.16.jpg)

Figure 5. (Buckyballs are strong, rigid natural molecules arranged in a series of interlocking hexagonal shapes, forming structures that resemble soccer balls). They are usually only a few nanometers in diameter, while the length can be up to a few centimeters. Nanotubes have high electrical conductivity ($10^{-6} \Omega\text{m}$) and high thermal conductivity (1750–5899 W/mK). As electrical conductors, nanotubes can carry high current densities (10^7 to 10^9 A/cm²). They are also inert and are not susceptible to corrosion by acids or alkalis (<http://nanotechweb.org/articles/news/4/10/7/1>; www.azonano.com/details.asp?ArticleID=980; Poole and Owens 2003; Ratner and Ratner 2002). Some applications of nanotubes in nanoscale communication are discussed briefly in the following sections.

Satellite Communication

Typical microwave amplifiers are based on thermionic emission sources, which tend to be bulky and heavy. Satellites are equipped with many such amplifiers, which add considerably to the weight, and hence it is expensive to launch a satellite. The thermionic emission source is also referred to as a hot cathode source. In essence, the hot cathode generates electrons that are modulated to produce electronic signals; these signals are processed to obtain the desired output. The efficiency of such systems is usually under 50 percent and decreases with increase in frequency. The thermionic emission source can be replaced by a nanotube device that acts as an electron source (de Jonge et al. 2005). The nanotube device is basically an array of equally sized and equally spaced nanotubes. When the nanotubes are exposed to an electric field, they release electrons from their tips. A radio-frequency wave is used to produce a high-frequency electron beam by exciting the nanotube array. The input signal is amplified by a process called “temporal modulation.” Frequencies of up to 32 GHz have been achieved. This novel system is both compact and relatively light compared to the conventional microwave amplifiers. The system can be instantly turned on and off. The efficiency is much higher than the hot cathode system because the

electrons are produced instantaneously at the nanotube source array (www.physorg.com/news8719.html).

Quantum Wires

Quantum wires, or nanowires, measure from one to a few nanometers in diameter, while the length is not restricted. Nanowires can be made out of metallic, semiconducting, or insulating materials. Molecular nanowires are made out of repeating molecular units. Nanowires tend to have relatively high resistance due to their narrow radii. Resistance-free propagation is possible only through relatively short distances, determined by the mean free path of carriers in the given material. However, carbon-nanotube-based nanowires have very low resistance. Nanowires are important components in nanoscale electronics and have many applications. For example, nanowires can be used to build transistors. A nanowire-based transistor has been developed by researchers at Harvard University (Xiang et al. 2006). Figure 6 illustrates the concept of nanowire-based transistors. These transistors can operate at least four times faster than their conventional silicon counterparts and can definitely boost computing and communication speeds of futuristic systems.

Actuators

Nanotube-based actuators are used to build optical switches. Current optical switches are generally electro-mechanical. These devices are prone to wear and tear and thus are not very reliable. Nanotube actuators do not have any sliding components and therefore need little maintenance and have much longer lifetimes. Figure 7 shows the difference between a mechanical actuator

and a nanotube-based actuator. The switching operation of these actuators use nanotube coated regions that can be made to selectively contract and expand. The differential strain produces the bending action (Lu and Panchapakesan 2005; Fukuda et al. 2004).

MICROELECTROMECHANICAL SYSTEMS (MEMS) AND NANOELECTROMECHANICAL SYSTEMS (NEMS)

MEMS are micrometer-sized mechanical components. Typically, MEMS lie outside the definition of nanodevices, as they are beyond the 100-nm range. They are briefly introduced here for the sake of completion, as some literature refers to them as nanodevices. Smaller components within the nanometer scale are referred to as nanoelectromechanical systems (NEMS). MEMS are manufactured using techniques very similar to semiconductor fabrication, and have a good likelihood of shrinking down to NEMS. Surface micromachining, bulk micromachining, electro-discharge machining, and etching are just a few of the manufacturing techniques used. MEMS are also referred to as micromechanics, micromachines, or microsystem technology (MST). Silicon is generally used to manufacture MEMS, but metals and polymers are also used.

Optical Networks

MEMS devices can be used as switches to route light from one fiber to another. The conventional method used to

Figure 6: Nanowire with silicon outer shell and germanium inner core (left); nanotransistor structure (right) (adapted from Xiang et al. 2006)

Figure 7: Mechanical switches and nanotube actuators (Dalton 2002)

route data to different fibers is to convert the light to an electrical signal using photodetectors, perform the routing, and convert it back to optical domain and transmit it to the destination fiber. Use of MEMS-based switches eliminates the need for the optical-to-electrical-to-optical conversion, which tends to be the biggest bottleneck in communication systems. The MEMS switches use an array of micromirrors to reroute photons to the desired fiber. The networks can thus be all optical, greatly boosting communication-system data rates. Active sources, tunable filters, variable optical attenuators, gain equalization, and dispersion compensation devices are other application of MEMS. The integration of these electronically controlled mechanical parts and mirrors is paving the way to a fairly new field in nanoscale applications called nano-electro-optical-mechanical systems, or NEOMS. NEOMS devices are expected to play a major role in the development of futuristic optical communications.

Resonators

Most electronic devices, including wireless communication devices, rely on resonators for frequency generation. The quartz crystal is a very popular material used for resonators. Despite being very reliable, crystal oscillators cannot be scaled down to nanometer scale. Electronic nanoscale communication devices require crystal oscillators for timing purposes, and if the quartz oscillator cannot be miniaturized, it would be impossible to develop such systems. MEMS can be used to manufacture resonators, thus allowing development of nanoscale resonators. There are many different types of MEMS resonators. One of these types—the dome resonator—is usually fabricated using a prestressed thin polysilicon film deposited over a sacrificial silicon dioxide layer. The resonant frequency of the film is a function of localized heating, which induces thermomechanical stress in the film. MEMS resonators can operate at hundreds of megahertz, whereas regular quartz crystals usually operate at around 30 MHz (www.mwrf.com/Articles/Index.cfm?Ad=1&ArticleID=5767).

Wireless Devices

Wireless communication is integrated in most mobile device, such as cell phones, personal digital assistants (PDAs), and laptops. Wireless communication uses many different schemes, such as time division multiple access (TDMA), code division multiple access (CDMA), third-generation (3G), global system for mobile [communications] (GSM), and Bluetooth. As technology progresses, novel wireless protocols will be developed. Because of politics or personal preferences, different organizations/countries use different wireless protocols. A mobile device moving from one region to another needs to be compatible with the wireless host protocol to stay connected to its base station, which is not always possible. Cell phones that are compatible with every wireless protocol currently in use are very expensive because the different radio-frequency (RF) components are expensive to integrate. Using RF-MEMS to replace conventional RF chips decreases price and size. Furthermore, the MEMS-based RF components are also more reliable and offer

better performance. Some RF-MEMS devices and their advantages are as follows:

1. *RF MEMS Switch*: Usually has very low insertion loss and can operate in the gigahertz region. One type of RF MEMS switch (shunt on silicon) has an insertion loss of 0.4 ± 0.1 dB at 90 GHz (Varadan 2003).
2. *RF MEMS Capacitor*: Has a high quality factor and great tunability (rendered possible by a movable MEMS structure). Capacitors can also be made using nanotubes, which greatly increases charge storage, since the nanotubes increase the effective surface areas. RF MEMS capacitors can operate up to 20 GHz (Varadan 2003).
3. *RF MEMS Inductor*: Has a high quality factor, high resonant frequency, up to 73 GHz, and is very compact in size (Varadan 2003).
4. *RF MEMS Filters*: Use of RF MEMS capacitors and RF MEMS inductors result in very compact high-quality filters.
5. *RF MEMS Phase Shifters*: Inexpensive to manufacture and more compact than the ferrite-based ones
6. *RF MEMS Transmission Lines*: Greatly reduce dielectric loss; any loss is due to the conductor material.

Reconfigurable Antennas

Reconfigurable antennas can switch the resonant frequency on the fly. To achieve such functionality, high-quality switches, variable capacitors, and inductors are needed. The conventional counterparts of these components cannot be used because they cannot be tuned automatically. However, the MEMS equivalent provides instantaneous tuning while maintaining a high quality. Reconfigurable antennas have many applications in wireless devices and satellites. Since nanoscale components are used, more functionality is added without compromising the size and weight.

NANOANTENNAS

Antennas basically focus and convert electromagnetic waves into an electric current. Radio waves and microwaves are the most common waves in the electromagnetic (EM) spectrum that are used for communication. The size of an antenna is related to the wavelength of the EM wave. Smaller EM waves allow smaller antennas. Using light as a carrier requires nanometer-sized antennas. Carbon nanotubes have been used successfully to convert light into an electric current. Such an antenna is on the nanometer scale and can be used for a multitude of applications. The fundamental function of an antenna is to focus the electromagnetic wave. An antenna that works with the frequency of light can also be used as a lens, since it focuses light. Researchers at University of Basel, Switzerland (Mühlschlegel et al. 2005) have successfully used gold strips to build an optical antenna. Contrary to conventional optical lenses, the nanoantenna has better optical resolution and can be integrated in nanoscale devices. Such nanoantennas can improve

the performance of conventional LEDs, single-photon sources, and optical communication networks.

DENDRIMERS

A dendrimer is a human-made molecule with a three-dimensional highly branched tree-like structure. The word *dendrimer* comes from the Greek word *dendra*, which means tree. A dendrimer molecule has a central core from which all the branches emanate. Each branch is referred to as a monomer. Dendrimers have unique electronic, optical, opto-electronic, and magnetic properties. They are very useful in nanoscale communication devices, particularly optical devices. Dendrimers are currently used to manufacture polymer electro-optic modulators, optical waveguides, photo-switching devices, and LEDs (Otomo et al. 2000; Kim et al. 2001; Markham et al. 2002).

ERBIUM-DOPED FIBER AMPLIFIER

The erbium-doped fiber amplifier (EDFA) is an “all optical amplifier,” and it is an extremely important component of the modern-day long haul fiber optic communication systems. It amplifies incoming optical signals without the need for optical-to-electrical conversion. EDFAs are made by doping low concentrations of erbium inside the core of the optical fiberglass substrate. They have low noise and polarization profiles with negligible interchannel cross talk and offer exceptionally high gain over short optical lengths. However, the efficiency of EDFAs tends to suffer because of collision broadening. Nanotechnology can play an important role in overcoming the problems associated with relaxation due to the collisions between erbium ions. This can be achieved by coating the erbium ions with a very thin layer of dendrimer that is approximately 8 to 17 Å in thickness. This dendrimer coating minimizes collision broadening to greatly increase the lifetime of the excited state of the erbium ions and leads to higher efficiencies.

NANO TRANSISTORS

Transistors are indispensable in digital electronics. VLSI circuits consist of millions of transistors, which are basically switches. The faster the switching speed, the faster is the computing speed of the system. The switching speed is a function of the length of the channel—the shorter the length, the lesser the distance traveled by the electrons and the faster the switching speed. Semiconductor technology is already operating in the 35-nm range. These devices require novel photolithography techniques, which can project structures of such small dimensions with minimal errors. A better technique to construct smaller transistors is to build them on the molecular scale. Literature review suggests that lately there has been a significant interest in the construction of nanotransistors using bacteria and DNA molecules.

Current semiconductor-based transistors are plagued by electronic-current-induced heating effects. Molecular transistors have extremely low power consumption;

they significantly lower heating, as they work with only a few electrons; and their switching speed is drastically improved. Communication devices use transistors extensively. The bandwidth of most optical communication links is limited by the switching speed of transistors and there is a difference of four orders of magnitude between the optical and electronic frequencies. Nanotransistors can theoretically bridge this gap.

Ballistic Transistors

Ballistic transistor is a term applied to transistors that allow electrons to flow at very high speeds without colliding with atoms, thereby removing the resistance encountered in conventional transistors. Currently, the preferred material for fabricating ballistic transistors is graphene. Physicists in the United Kingdom and Russia have successfully used graphene sheets one atom thick to fabricate ballistic transistors (Novoselov et al. 2004). These transistors can operate at room temperature and allow electrons to flow without being scattered by atomic collisions. However, the current operating frequency of the device is low (Walters, Bourianoff, and Atwater 2005; Xiang et al. 2006).

Spintronic Transistors

A spintronic transistor uses the spin of an electron. According to quantum physics, an electron can exhibit only one of two states: either spin up or spin down. The spin of the electron is used to encode information. Unlike conventional transistors, the state of the spintronic transistor can be changed without the use of electric current. Consequently, power requirements are drastically reduced. In 2005, researchers at the University of Basel, Switzerland, developed a spintronic transistor using a single carbon nanotube by connecting two magnetic electrodes to alter the spin of the electrons (Babic, Iqbal, and Schönenberger 2003).

Quantum Interference Effect Transistors (QuIET)

Though still in the experimental stages, the quantum interference effect is a very promising technique to produce nanotransistors. The duality principle states that a particle can behave both as a particle and a wave. On the nanoscale level, these particles or waves interfere with each other. This process is called “quantum interference.” A QuIET-based single molecule has been developed at the University of Arizona (Cardamone, Stafford, and Mazumdar 2005). The device consists of an organic ring molecule that has two electrodes attached at the meta positions, as illustrated in Figure 8. Such an arrangement produces quantum interference, which cuts the flow of current, turning off the transistor. The QuIET is switched off by the presence of quantum interference. Conversely, the device is switched on when quantum interference disappears. Such a state is called a “decoherence.” At present, decoherence is produced by either bringing the tip of a scanning tunneling microscope close to the molecule or by attaching a donor molecule, in which case the

Figure 8: QuET transistor with organic ring and donor molecule (adapted from Cardamone, Stafford, and Mazumdar 2005)

polarization of the donor molecule controls the decoherence. Such a molecular device is expected to shrink the size of communication components and is definitely a promising step toward molecular computing devices.

MACH-ZEHNDER MODULATORS

Modulation of optical or electrical signals is fundamental to conveying information across physical channels. A very popular optical modulator is the Mach-Zehnder modulator, which uses the Mach-Zehnder interferometer. A laser beam is split into two at a Y-junction (optical coupler) and then recombined at another junction. The output of such a system depends on the difference of the optical path length of the two split beams of light. Any relative difference can be used to produce a modulated output. The modulated output is a function of the interference between the two signals. Figure 9 illustrates a simple implementation of the Mach-Zehnder modulator. This modulator modifies the phase of one of the signals in order to modulate the output.

Typical materials used to manufacture small-scale Mach-Zehnder modulators include GaAs, AlGaAs, InP, InGaAsP, and other III-V materials. These materials have wide bandgap with higher carrier mobility and higher electron-photon interaction probability (Verdeyen 1995).

SILICON PHOTONICS

Silicon photonics is an evolving field that has gained significant momentum in the communications area and has the potential to fulfill many of the requirements necessary for

faster and more reliable optical communication. Silicon already dominates the semiconductor industry because of its availability, good thermal and mechanical properties, and ease of manufacturing. Among other things, the speed of communication links is limited by the computation power, which is dependant on the semiconductor circuits. Transistor miniaturization is approaching the point of diminishing returns. Even if we could pack more transistors on a single chip, the delays due to coupling, signal latency, and signal cross talk will greatly hamper the operating frequency of the device. A potential solution to this problem is silicon photonics. Photonic integrated circuits are inherently immune to electrical signal cross talk and resistor-inductor delays. Using photonic circuits for computers will lead to the cherished goal of optical computing, while their applications to communication links can result in greatly enhanced operating speeds and reliability. Examples of components required for photonic integrated circuits, needed for communication, are briefly discussed below. Most of these components are already on the nanoscale (Ossicini, Pavesi, and Priolo 2004).

Silicon Waveguides

One of the most important components in silicon photonics is the waveguide. Silicon has desirable refractive index, good electro-optical properties, and low losses. However, the size needs to be comparable to a complementary metal oxide semiconductor (CMOS) device, to allow integration of a large number of components on a single chip. Silicon nitride-based waveguides (Bulla et al. 1999) and

Figure 9: Simple Mach-Zehnder modulator

Figure 10: Raman laser developed by Intel

silicon oxynitride waveguides (Hilleringmann and Goser 1995) show losses lower than 0.5 dB cm^{-1} at 633 nm and bending radii of less than 200 μm . Silicon-on-insulator (SOI) is another popular combination of materials that is used as waveguides. Such waveguides have optical losses as low as 0.1 dB cm^{-1} at 1.55 μm (optical mode cross section, $0.2 \times 4 \mu\text{m}^2$) (Masini et al. 1999; www.intel.com/technology/silicon/sp/index.htm; Charlton, Roberts, and Parker 1997; Pavesi 2003; Salib et al. 2004).

Silicon Modulators

Silicon-based modulators are inexpensive to produce but until recently commercially available silicon modulators were limited to about 20 MHz. This speed was insufficient, given that most Ethernet adapters already work in the gigabit region. In 2004, Intel developed a silicon-based optical modulator that is similar to a transistor. The required phase shift for modulation is induced by an electrical charge. The device can operate at 1 GHz, and research suggests that the technology can be scaled up to operate at about 10 GHz. Additionally, there are indications that silicon photonics may also find application in microprocessors in addition to nanoscale communication.

Silicon Nanocrystals

Silicon nanocrystals have better optical properties than bulk silicon. When a nanocrystal is in the excited state, both the electrons and the holes are spatially confined and are at higher potential energy. The electron-hole pair combines to form an exciton that decays to release a photon. This property makes the silicon nanocrystal a good candidate to manufacture modulators, optical amplifiers, and light-emitting diodes. In 2005, researchers at California Institute of Technology successfully manufactured a transistor that emits light using bulk silicon and silicon nanocrystals ranging from 2 to 4 nm in size (Walters et al. 2005). The size of the nanocrystal determines the color of the emitted light. The device is called a “nanocrystal field-effect light-emitting device (FELED),” and it consumes very little power.

Silicon Lasers

Silicon nanocrystals can also be used to manufacture lasers. In 2005, Intel reported the development of one such laser (Rong et al. 2005). The Raman effect and the silicon

crystalline structure are used to amplify the signal as it passes through the device. Though this device is still in a developmental stage, the applications are endless. Figure 10 illustrates this device (Claps et al. 2004; Pavesi, Gaponenko, and Dal Negro 2003).

TERAHERTZ LASERS

The 4- to 10-THz range, also known as the 30- to 75- μm very long wavelength infrared region, is currently not exploited because there are no devices that operate at these frequencies. A purely experimental chip-based laser operating at 4.4 THz has been developed by researchers from Italy and England (Kohler et al. 2002). It is a quantum cascade device made from a stack of around 1500 alternating layers of gallium arsenide and aluminum gallium arsenide totaling a thickness of 12 μm such that most of the individual layers are on the nanoscale. An electronic staircase is built and electrons bounce down the staircase releasing a photon at each step. However, currently this device operates only at very low temperatures. Research is being done to allow operation at higher temperatures. Such a device is expected to play an important role in futuristic communications because of its high operating frequency.

Surface Plasmons

Surface plasmons exist at the interface between a metal and a dielectric. Plasma oscillations are periodic oscillations of charge density in metals or plasmas. The particle (quasiparticle to be more precise), resulting from quantization of plasma oscillations is the plasmon. Surface plasmon resonance occurs when the surface plasmons are excited by light. The optical properties of metals are greatly influenced by plasmons. Light with frequency less than the plasma oscillations is reflected, whereas light with higher frequency is transmitted. Since plasmons can support frequencies up to hundreds of terahertz, they can be used to replace wires on computer chips. Because of their small wavelengths, they can also be used for nanolithography. Since plasmons interact with light, they can have numerous applications in optical communication. For example, in May 2006 a VCSEL based on surface plasmon resonance was developed by Matsushita Electric Industrial Co., Ltd. The main feature of this VCSEL is an array of silver nanoholes on a “surface plasmon mirror.” Such a VCSEL has a high power output and can be used

for high-speed and short-distance optical communication like optical interconnection and plastic fiber communication. In addition, in March of 2006 physicists in France and Denmark developed an optical waveguide based on surface plasmons. The waveguide allows light to pass through channels smaller than the wavelength of light without significant attenuation (Bozhevolnyi et al. 2006). Such surface-plasmon-based waveguides have tremendous potential applications in photonic circuits and optical communication. Lately, surface-plasmon-based nanophotonics is generating lots of interest among the research community, and it promises to play a key role in enabling high-density optical communications at the nanoscale (Bozhevolnyi et al. 2006).

CONCLUSION

Applying nanotechnology to communication devices can revolutionize communications and networking environments. Nanoscale devices can boost data rates and help tap the full potential of currently used communication media. If photons were used on computers as information carriers, there would be no need for any electrical-to-optical interface. Such development will also allow full utilization of the potential of optical fibers. For example, silicon photonics, photonic crystals, and MEMS can convert existing optical fiber communication links to an "all optical system" by eliminating the electrical-to-optical interface, which tends to be the biggest bottleneck in modern optical communication systems. Research in the field of silicon photonics and surface plasmons have brought the idea of optical computing closer to reality. Although optical computing and optical networks are ideal for high-speed communications, current transistor-based systems can still achieve higher speeds with the advent of practical nanotransistors. Ballistic transistors, spintronic transistors, and quantum interference effect transistors are expected to boost the operating frequency of transistors. Similarly, fruition of research in quantum computing and quantum cryptography promises to immunize networks from malicious activities such as eavesdropping. In short, nanotechnology can make the current networking environment faster, more efficient, and virtually impenetrable. The next logical step appears to be the development of intelligent, self-healing communications devices that can adapt to meet bandwidth and load requirements with little human intervention.

GLOSSARY

Dendrimer: Synthetic material with unique electrical, optical, and opto-electric properties.

Erbium-Doped Fiber Amplifier: Very compact and efficient amplifier.

Microelectromechanical System: Also known as MEMS. They have various applications in wireless communication.

Nanotube: Can be used for satellite communication, nanowires, and actuators.

Photonic Crystal: Multidimensional periodic dielectric nanostructures designed to control and manipulate the propagation of electromagnetic waves. Can be used to

manufacture various optical components in communication devices.

Quantum Dot: Can be used for single-photon sources and detectors.

Silicon Photonics: Using silicon-based materials to develop optical components, such as waveguides, modulators, and lasers that can be used to manufacture photonic integrated circuits.

Surface Plasmons: Exist at the interface between a metal and a dielectric. They have application in VCSELs and optical waveguides.

Vertical Cavity Surface Emitting Laser: Emits its infrared energy perpendicular to semiconductor layers.

INTRODUCTION

Biological nanomachines (or “nanomachines,” for short) are nanoscale and microscale devices that either exist in the biological world or are artificially created from biological materials (i.e., molecules) and that perform simple functions such as sensing, logic, and actuation. Molecular communication is a new paradigm for communication between nanomachines over a short (nanoscale or microscale) range. It is the process of communication between nanomachines through encoding information onto molecules, rather than electrons or electromagnetic waves, and exchanging the molecules between nanomachines (Hiyama, Moritani, and Suda 2006). Using electrons or electromagnetic waves for communication is particularly limited at the nanoscale and microscale range because of power constraints and limitations in the size of communication components. Because nanomachines are too small and simple to communicate using electrons or electromagnetic waves, molecular communication provides a novel mechanism for nanomachines to communicate by propagating molecules that represent the information.

In biological systems, a nanomachine (such as a cell or a protein complex) is a basic building block of organisms, and nanomachines use various forms of molecular communication to transmit information to other nanomachines. For instance, cells communicate by

releasing hormones into the bloodstream, exchanging Ca^{2+} ions through protein channels, or transferring DNA instructions. Some nanomachines in biological systems also have the ability to self-replicate (through, for instance, biological cell reproduction) and to self-assemble into organisms that coordinate through molecular communication. The nanomachines communicate with hormones to activate and synchronize the activity of replication and nanomachine organization. Existing research on artificially creating (or engineering) molecular communication is based on understanding the design of molecular communication in biological systems and on modifying the functionality of existing molecular communication in biological systems. Creating molecular communication, thus, represents an interdisciplinary research area that spans the areas of biology, nanotechnology, and computer science.

This chapter is organized in the following manner. The remainder of this section describes possible applications of molecular communication, the key components and phases of molecular communication, and key characteristics of molecular communication. Then we describe molecular communication that occurs in biological systems. We go on to discuss existing research in engineering molecular communication and to describe existing research to engineer a molecular communication network—that is, a system of communicating nanomachines.

Applications

Molecular communication integrates techniques from biology to interact with biological systems, from nanotechnology to perform nanoscale and microscale interactions, and from computer science to integrate into larger-scale information and communication processing. Molecular communication has significant potential, since it interacts directly with biological systems at nanoscales and microscale and may enable new applications through integrated nanomachines.

Molecular communication may impact how nanomachines interact with biological systems (Montemagno 2001). For instance, a biological system (e.g., the human body) is composed of a large number of cells (i.e., nanomachines). Each cell performs simple and specific operations such as uptake, processing, and release of molecules. Cells interact to perform various functions of the body (e.g., distributing molecules for metabolism and replication of cells). Molecular communication provides mechanisms to transport molecules between cells, and thus, it may help perform targeted delivery of drugs by providing mechanisms to transport drugs (information-encoded molecules) between drug repositories embedded in the human body (sender nanomachines) and specific cells in the human body (receiver nanomachines). Molecular communication also provides mechanisms for nanomachines to communicate, and thus, it may help drug repositories (sender nanomachines) to coordinate and control the amount and timing of drug release. Targeting delivery of drugs to specific cells in a human body and creating molecular communication for such applications involve understanding how molecules are transported within a biological system, how molecules are addressed to specific locations within a biological system (i.e., molecule-addressing mechanisms in a biological system), or even adding receptor molecules to a biological system to produce an addressing mechanism (Langer 2001; Pappas and Huang 2004; Allen and Cullis 2004). Molecular communication may eventually provide a mechanism to interact with the human body at the molecular level (Moritani, Hiyami, and Suda 2006, Molecular communication for health care applications).

Molecular communication may impact the size and the complexity of systems that nanomachines can form. Nanomachines (both naturally existing in biological systems and artificially created from biological materials with existing technology) are limited to performing simple functions (i.e., sensing, logic, and actuation). Nanomachines with simple functions may communicate with nearby nanomachines through molecular communication; thus, the nanomachines can self-organize into larger machines with more complex functions (Balzani, Venturi, and Credi 2003). For instance, nanomachines may communicate and coordinate through molecular communication to amplify a signal starting at the nano scale into a signal detectable at the human scale.

Molecular communication may impact what forms of information may be exchanged among nanomachines. It may also allow transmission of information that cannot be readily represented in a digital format, such as chemical composition of cells or emotion (represented as the chemical state of human brain and body). It may also transmit molecules storing energy or heat.

Overview of Molecular Communication

The generic molecular communication (Figure 1) consists of components functioning as information molecules (i.e., molecules such as proteins or ions) that represent the information to be transmitted (Smith 2000), sender nanomachines that release the information molecules, receiver nanomachines that detect information molecules, and the environment in which the information molecules propagate from the sender nanomachine to the receiver nanomachine (Suda et al. 2005; You et al. 2004). It may also include transport molecules (e.g., molecular motors) that transport information molecules, guide molecules (e.g., microtubule or actin filaments) that direct the movement of transport molecules, and interface molecules (e.g., vesicles) that allow any type of information molecule to be transported by a transport molecule (Moritani, Hiyami, and Suda 2006, Molecular communication among nanomachines using vesicles).

Figure 1: Phases of a molecular communication: (1) a sender nanomachine encodes information onto information molecules, (2) the sender nanomachine releases the information molecules into the environment, (3) the information molecules propagate in the environment by diffusion or with direction by binding to transport molecules, (4) a receiver nanomachine with appropriate receptors receives the information molecules, (5) a receiver chemically interacts with the information molecules and decodes information.

Components of molecular communication are made up of molecules, and must be designed with the thought in mind that molecular communication occurs in an aqueous or air environment, which generates a significant amount of noise. The noise in the environment comes from a number of factors. For instance, the environment contains energy and forces that constantly interact with the various molecular communication components. Such energy and forces include thermal energy, electrical fields, magnetic fields, and electromagnetic waves (e.g., light energy that is absorbed by molecules). The environment also contains molecules and nanomachines that do not participate in molecular communication, and these generate noise. Such molecules and nanomachines include solvent molecules (e.g., water molecules), solute molecules (e.g., energy molecules necessary to support the nanomachines), and other nanomachines (e.g., nanomachines to maintain chemical concentrations in the environment or act as structural components). The noise in the environment determines the degree of randomness in molecular communication (e.g., randomness in the movement of information molecules and randomness in the timing of, rate of, and energy for chemical reactions).

The components in molecular communication perform the following general phases of communication (Figure 1): encoding of information into an information molecule by the sender nanomachine, sending of the information molecule into the environment, propagation of the information molecule through the environment, receiving of the information molecule by the receiver nanomachine, and decoding of the information molecule into a chemical reaction at the receiver nanomachine.

Encoding

Encoding is the phase during which a sender nanomachine translates information into information molecules that the receiver nanomachine can detect. Information may be encoded onto the type of information molecules used. Information may also be encoded in various characteristics of information molecules such as the three-dimensional structure of the information molecule, in the specific molecules that compose the information molecules, or in the concentration of information molecules (the number of information molecules per unit volume of solvent molecules).

The amount of information that a sender encodes onto a single information molecule is limited by the molecular structure of a receiver nanomachine. A receiver nanomachine is capable of only a limited number of configurations; thus, when a receiver nanomachine receives an information molecule, the receiver nanomachine receives only the amount of information corresponding to the number of configurations possible in the receiver nanomachine (Schneider 1991). If a receiver nanomachine achieves only two configurations, the receiver nanomachine only understands one bit of information at a time.

A sender nanomachine may transmit information about which a receiver nanomachine does not have information. For instance, in biological systems, certain types of cells communicate through exchanging

DNA molecules. An arbitrary DNA sequence is decoded at a receiving cell into proteins that introduce new functionality into a receiver cell. If a sender nanomachine in molecular communication can transmit arbitrary information molecules, it is possible to send new functionality to the receiver nanomachine.

Sending

Sending is the phase during which a sender nanomachine releases information molecules into the environment. A sender nanomachine may release information molecules by either unbinding the information molecules from the sender nanomachine (e.g., by budding vesicles from a biological cell if a sender nanomachine is a biological cell with endoplasmic reticulum), or by opening a gate that allows the information molecule to diffuse away (e.g., by opening a gap junction channel in the cell membrane of a sender nanomachine). A sender nanomachine may also catalyze a chemical reaction that produces transport molecules elsewhere.

Because of its size, a sender nanomachine contains a limited amount of energy and information molecules. This results in a limited communication capability that the single sender nanomachine alone can generate. Thus, the sender nanomachine of molecular communication generally relies on the environment for supplying (chemical) energy and information molecules. In addition, multiple sender nanomachines may release the same information molecules, resulting in a stronger signal in the environment.

Propagation

The sender and receiver nanomachines are at different locations in the environment, and propagation is the phase during which the information molecule moves from the sender nanomachine through the environment to the receiver nanomachine. The information molecule may diffuse passively through the environment without using chemical energy or may bind to a transport molecule (e.g., a molecular motor that generates motion [Barron, Gu, and Parillo 1998]) and actively propagate through the environment using energy.

In passive transport, information molecules randomly move according to forces in the environment. Large information molecules or high-viscosity environments result in slower diffusion through the environment. In active transport, a transport molecule carries information molecules through the environment, and it consumes chemical energy to reduce the randomness in its movement in the environment. By providing more control over the movement of information molecules, active transport may decrease the time necessary for information molecules to reach the receiver nanomachine and also increase the probability of information molecules successfully reaching the receiver nanomachine.

During propagation, an interface molecule may also be necessary to protect information molecules from noise in the environment. For instance, information molecules may be contained in a vesicle-based interface molecule and propagate through the environment (Moritani, Hiyami, and Suda 2006, Molecular communication among nanomachines using vesicles).

The vesicle prevents the information molecules from chemically reacting with other molecules outside the vesicle.

Receiving/Decoding

Receiving is the phase during which the receiver nanomachine captures information molecules being propagated in the environment. Decoding is the phase during which the receiver nanomachine, upon capturing information molecules, decodes the received molecules into a chemical reaction. One option for capturing information molecules is to use receptors that are capable of binding to a specific type of information molecule. Another option for capturing them is to use channels (e.g., gap-junction channels) that allow them to flow into a receiver nanomachine without using receptors. Chemical reactions for decoding at the receiver nanomachine may include producing new molecules, performing a simple task, or producing another signal (e.g., sending other information molecules).

Because of possible noise in the environment and also because of possible errors in receiving information molecules, molecular communication may not rely on sending a single information molecule. For instance, in biological systems, a sender nanomachine (e.g., a cell) and a receiver nanomachine (e.g., another cell) exchange a number of information molecules, and the receiver nanomachine has a number of receptors to detect the concentration of information molecules. There are also often a number of sender and receiver nanomachines that each has the capability of sending, detecting, and chemically reacting to information molecules.

Similar to computer networks, in which a layering architecture separates concerns of communication, molecular communication in biological systems may be viewed in terms of a layered architecture. At the lowest layer (the physical layer) in computer networks, information is encoded onto electrons and electromagnetic waves. In molecular communication, information is encoded onto information molecules (e.g., onto the types of the information molecules used, in various characteristics of information molecules, or onto the concentration of the information molecule). At the second layer (the data-link layer) in computer networks, information is transmitted reliably between neighboring computers through feedback (e.g., flow-control acknowledgment). In molecular communication, biological systems often use positive and negative feedback to reliably control the number of information molecules released. In biological systems, communication to a specific receiver is achieved through molecular-level addressing. For instance, a mechanism for addressing is through the type of information molecule and the type of receptor used (i.e., a sender nanomachine uses a certain type of information molecules to send to a receiver nanomachine, and the receiver nanomachine has receptors to chemically react to the type of information molecules that the sender nanomachine uses) or through the three-dimensional distribution of the information molecules (e.g., during organism development processes, sender nanomachines establish chemical concentrations around themselves, and nearby receiver nanomachines

react to the detected chemical concentrations to form patterns of receiver nanomachines). Existing molecular communication research is primarily concerned with these lower two layers, and thus, this chapter discusses issues at these two lower layers.

Characteristics of Molecular Communication

A variety of molecular communication's characteristics result from using nanomachines as senders and as receivers, using molecules as an information carrier, and from the propagation of information molecules through an aqueous environment. First, the size of nanomachines contributes significantly to their limited functionality, including functionality available for communication. Second, the aqueous environment generates a significant amount of noise; thus, it is difficult for nanomachines to operate reliably in the environment and for humans to control individual nanomachines (Service 2001). Environment noise also causes the propagation of information molecules to be fundamentally stochastic and to have a relatively long communication delay. Third, since information is encoded onto molecules in molecular communication, the amount of information that a receiver nanomachine receives is limited by the number of possible configurations in the receiver nanomachine. In addition, a sender nanomachine may transmit information about which a receiver nanomachine does not have information. Thus, molecular communication may have characteristics of nonbinary encoding. Fourth, the biological molecules and materials used to create components for molecular communication cause that communication to exhibit characteristics of asynchronous communication, biocompatibility, and energy efficiency. Each of the unique characteristics of molecular communication is described below.

Stochastic

The stochastic behavior of molecular communication arises from environmental factors such as unpredictable movement of molecules in the environment, as well as from communication component factors such as nanomachines stochastically reacting to information molecules and nanomachines and information molecules degrading over time. Environmental factors and communication component factors inherently affect the design of molecular communication. For instance, in order to be robust to the environmental noise, the sender nanomachines increase the signal-to-noise ratio by releasing a large number of information molecules, and receiver nanomachines chemically react to information molecules only when a relatively large number of information molecules are present in the environment. Sending a large number of information molecules is highly redundant, so that degradation of a few information molecules during propagation does not impact communication. In addition, non-information molecules (noise-causing molecules) in the environment may not trigger chemical reaction at a receiver nanomachine as long as the noise from those molecules is significantly less than the signal from a large number of information molecules.

Delay

Molecules in the environment that do not participate in molecular communication cause information molecules to propagate slowly through the environment. In both passive and active transport, the speed of propagation is bounded at a relatively lower speed (i.e., micrometers per second in an aqueous environment) because of the large amount of interference with the molecules in the environment. In addition, because of the possibly large delay in the environment, information molecules may remain in the environment for a period of time and arrive at a receiver nanomachine after a widely varying amount of time (e.g., hours after release at the sender nanomachine).

The delay in an information molecule propagating from a sender to a receiver nanomachine determines various communication characteristics of molecular communication. If the information molecules stay in the environment for an extended length of time (e.g., DNA molecules can be chemically stable for months), a sender nanomachine must delay a new communication until the information molecules used in an old communication degrade in the environment to prevent the old communication from interfering with the new communication. "Thus, the frequency at which a sender nanomachine send information is limited by the length of time information molecules stay in the environment" before degrading.

Nonbinary Encoding

As explained in the section on "Overview of Molecular Communication," in molecular communication, information may be encoded onto the type of information molecules used. Information may also be encoded in various characteristics of information molecules such as the three-dimensional structure, chemical structure (e.g., protein), sequence information (e.g., DNA), or concentration (e.g., calcium concentration) of information molecules (Schneider 1991). A physical substance (i.e., the information molecule) propagates from a sender nanomachine to a receiver nanomachine, and the receiver nanomachine chemically reacts to incoming information molecules. Because information is encoded onto molecules in molecular communication, the amount of information that a sender encodes onto a single information molecule (or the amount of information that a receiver nanomachine receives) is limited by the number of possible configurations in the receiver nanomachine. In addition, a sender nanomachine may transmit information about which a receiver nanomachine does not have information. Thus, information molecules in molecular communication can encode information that is not readily represented by binary encoding.

Asynchronous Communication

Molecular communication in biological systems is asynchronous. Sender and receiver nanomachines in biological systems do not require a synchronizing signal. A sender nanomachine releases information molecules independently from other sender nanomachines and from receiver nanomachines, which react to the incoming information molecules on receiving the information

molecules. For instance, the concentration of glucose (a metabolite consumed as energy by cells) is determined asynchronously by separate groups of cells that perform specific functions to maintain homeostasis (i.e., stable chemical concentrations). These groups of cells communicate through the concentration of the glucose and determine independently what chemical process to perform to produce or consume it without requiring a synchronization signal.

Biocompatibility

Sender and receiver nanomachines in molecular communication communicate through sending, receiving, and decoding (chemically reacting to) information molecules. Since molecular communication uses the same communication mechanisms as biological systems, nanomachines in molecular communication can directly communicate with various natural components in a biological system using encoding and decoding methods available to the biological system. Biocompatibility of molecular communication may enable applications such as inserting nanomachines into a biological system for medical applications that require biologically friendly nanomachines.

Energy Efficiency

Through the fine-tuning of natural evolution, molecular communication in biological systems has achieved a high degree of energy efficiency. For example, under some conditions, myosin (a type of a molecular motor) converts chemical energy (i.e., ATP) to mechanical work with 90 percent energy efficiency (Howard 2001; Yasuda et al. 1998). Energy efficiency may be useful to reduce the energy cost of using nanomachines for applications in which the human body is the energy source or for low-cost production of objects.

OBSERVATIONS OF MOLECULAR COMMUNICATION IN BIOLOGICAL SYSTEMS

Molecular communication is a common communication method in biological systems for transmission of information between biological nanomachines (Dixon 1990; Lee and Chang 2003). In biological systems, information molecules propagate through passive transport (using random movement of molecules caused by thermal energy) and through active transport (using transport molecules that consume energy to transport information molecules). This section describes some representative examples of nanomachines and molecular communication in biological systems.

Molecular communication in biological systems occurs at multiple scales. For instance, at the nanoscale, a protein complex may chemically react with another protein complex using a single type of information molecule. At the microscale level, a cell may communicate with other cells through one or more types of information molecules. At the system level, a group of cells (e.g., microbe/bacterial cells) form a group of sender nanomachines that communicate with another group of cells (a group of receiver nanomachines) (Zhou et al. 2005).

Biological Nanomachines in Biological Systems

There are a number of nanomachines found in biological systems. Cells and various molecules inside a cell (e.g., DNA, RNA, and proteins) are at nanoscale or microscale and perform simple functions (such as replication, movement, and metabolism) and are all examples of nanomachines in biological systems. Cells are the basic building blocks in biological systems (Alberts et al. 2002). They are capable of sending and receiving information molecules. For instance, in bacterial conjugation, a sender bacterium extends a pilus that attaches to a receiver bacterium and the sender bacterium transports DNA (i.e., a plasmid encoding a set of proteins) through the established pilus to the receiver bacterium. The plasmid may encode various useful proteins such as antibiotic resistance, allowing the receiver bacteria to acquire new functionality.

Many molecules inside a cell are nanomachines and interact with other molecules inside the cell. For instance, DNA inside a cell interacts with other molecules within the cell (Figure 2) to produce messenger RNA (mRNA) through a process called “transcription,” and the mRNA produced interacts with tRNA to synthesize a chain of amino acids (a protein), through a process called “translation.” In this example, DNA represents a sender nanomachine that generates (i.e., encodes) and sends mRNA, and tRNA represents a receiver nanomachine that receives mRNA and synthesizes (i.e., decodes) a protein.

Communication Processes in Biological Systems

Biological nanomachines in biological systems exhibit a wide variety of mechanisms for exchanging information at

Figure 2: Biological nanomachines in a cell: DNA sequences are transcribed into mRNA sequences. mRNA sequences are translated into proteins using tRNA. DNA, mRNA, and proteins interact and regulate the transcription/translation of the cell. DNA represents a sender nanomachine that encodes information onto mRNA and sends mRNA, mRNA represents the information molecule, and tRNA represents a receiver nanomachine that receives mRNA and decodes the information into a sequence of amino acids (i.e., a protein). Through these regulatory processes, a cell controls its functions such as metabolism, growth, and repair. These information molecules are contained inside a lipid bilayer cell membrane.

the nanoscale and the microscale, including mechanisms for intracellular transport (to transport molecules within a single cell) and for intercellular transport (to transport molecules between cells). Sender and receiver nanomachines exist in biological systems in a wide variety of forms at the nanoscale and the microscale. In intracellular transport, sender and receiver nanomachines are components within the cell, and information molecules are ions, peptides, mRNA, and other metabolites (i.e., consumable molecules in the environment or products of chemical reactions). For intercellular communication, the sender and receiver nanomachines are cells, and information molecules are ions, peptides, metabolites, or DNA.

For intracellular transport, information molecules are transported inside a biological cell. For instance, an inert vesicle that contains the neurotransmitter acetylcholine is transported to the end of a neuron for chemical reaction. For small molecules, passive diffusion is sufficient to randomly move the information molecules. However, for large molecules that do not diffuse well, the cell requires molecular motors (e.g., myosin, kinesin) to actively transport large molecules within the cell. A molecular motor is a protein or a protein complex that converts chemical energy (e.g., ATP hydrolysis) into mechanical work at the molecular scale (Figure 3). Inside a cell, molecular motors transport large information molecules or large vesicles (e.g., liposomes, cell organelles) that contain information molecules (Oiwa and Sakakibara 2005; Shima et al. 2006; Toba and Oiwa 2006). Molecular motors consume chemical energy (e.g., ATP) to transport the information molecules or the vesicles along the preestablished guide molecules (e.g., along a star-shaped topology that the guide molecules form inside a cell). A vesicle acts as an interface molecule that can store a variety of information molecules. It provides an inert container so that the information molecules inside the vesicle do not cause chemical reactions until they reach the receiver nanomachine. For instance, inside some neuron cells, molecular motors (e.g., kinesin and dynein) transport vesicles

Figure 3: Transport of a vesicle by a molecular motor: A kinesin molecule is a type of molecular motor. The kinesin molecule consumes chemical energy (i.e., ATP) to mechanically walk in one direction along a microtubule inside a cell. The molecular motor can selectively bind to vesicles and thus transport a vesicle containing information molecules.

containing acetylcholine along cytoskeletal tracks in the axon of the neuron. The transported acetylcholine is released at the end of the axon and causes a response in the adjacent neuron with a receptor for acetylcholine (Alberts et al. 2002).

In the intercellular transport, biological cells use various mechanisms to transport information molecules (e.g., peptides or ions) among cells. For short-range communication (within a few cell lengths away) among cells, cells release information molecules (e.g., proteins and peptides) into the extracellular environment, and neighboring cells capture the information molecules with protein receptors (e.g., G-protein-linked receptors, enzyme-linked receptors, and ion-channel-linked receptors), thus resulting in the activation of a chemical reaction (e.g., increased metabolism or transcription of cellular proteins). Another type of short-range communication between cells is through physical contact using cell-cell junction channels such as gap-junction channels. Gap-junction channels allow connected cells to share small molecules such as Ca^{2+} (calcium ions), and therefore, enable coordinated actions among adjacent cells in response to extracellular signals (Alberts et al. 2002).

For long-range intercellular communication cells communicate through the environment by sensing and modifying molecules of the environment (Alberts et al. 2002; Devlin 2001; Mathews, van Holde, and Ahern 1999; Nelson and Cox 2000). One example of intercellular communication is the regulation of thyroxine. The overall process of thyroxine regulation represents a homeostatic system in which multiple cells communicate with each other through the concentration of a certain chemical substance in the environment. Thyroxine is a hormone that invokes the process to control the basal metabolic rate of cells. The process of regulating thyroxine concentration involves two glands—the pituitary and the thyroid. Cells in the pituitary gland called “thyrotropes” (Villalobos, Nunez, and Garcia-Sancho 2004) secrete thyroid-stimulating hormone (TSH). The secreted TSH propagates through the blood circulation system to cells throughout the body. Upon receiving TSH, the epithelial cells of the thyroid gland produce thyroxine. When the thyroxine concentration becomes too high, the pituitary gland decreases the secreted amount of TSH, and this, in turn, causes epithelial cells of the thyroid gland to produce less thyroxine. Through this interactive process between the pituitary gland and thyroid gland, the thyroxine concentration is stabilized in the human body.

Another example of the intercellular transport (i.e., cellular communication among multiple cells) is quorum sensing. Bacterial cells perform quorum sensing by releasing an autoinducer, acyl homoserine lactone (AHL), and detecting the concentration of AHL, to estimate the number of nearby bacteria. AHL released by bacteria diffuses through the environment. When the AHL concentration is sufficiently high in the environment, the bacteria interpret this as a large number of bacteria in the environment, and thus, the bacteria start transcribing DNA to perform group functions (e.g., enough bacteria to generate an infection, form a biofilm, or generate luminescence) (de Kievit and Iglewski 2000).

Yet another example of the intercellular transport (i.e., cellular communication among multiple cells) is the transmission of genetic information stored in DNA between cells. For instance, a bacterium transmits DNA to another bacterium through the process of conjugation. In the process of DNA transmission, two types of bacteria, a sender bacterium with an F-plasmid (i.e., a genetic sequence that enhances the transfer of genetic information) and a receiver bacterium without F-plasmid, transfer a DNA chromosome through a pilus (i.e., a projection from the sender bacterium to the receiver bacterium forming a bridge for transmitting DNA). Transfer of DNA between bacteria may allow the receiver bacterium to acquire DNA that produces some useful cellular functionality (e.g., protein production, antibiotic resistance). Bacteria also move through the environment (using molecular motors such as flagella or cilia), and thus, may transport DNA or other information molecules to other bacteria in the environment (Tamarin 1999; Berg, Tymoczko, and Stryer 2002). The receiver bacterium may also release pheromones that form a chemical gradient that guides a sender bacterium toward a receiver bacterium (i.e., the closer to the receiver, the higher the chemical concentration).

Passive Transport-Based Molecular Communications in Biological Systems

Examples of passive transport of information molecules in biological systems include diffusion of molecules among organisms or communication between adjacent cells through gap junctions, described in the section on “Biological Nanomachines in Biological Systems.” Passive transport of information molecules provides a simple and robust method of propagating information in biological systems. It is simple, as it does not require a transport molecule that chemically reacts with energy molecules. It is robust, as it functions even if the environment drastically changes.

Some passive transport uses free diffusion and transmits in all available directions. This makes diffusion-based passive transport independent of the position of the receiving nanomachines in the environment, making it particularly suited to environments that are highly dynamic and unpredictable. Diffusion-based passive transport is also suited to situations in which infrastructure for communications is not feasible between a sender and a receiver. For instance, plants release pheromone molecules into the air to signal other plants without using any preestablished infrastructure (Lucas and Lee 2004). The sender plant communicates information regarding attacks from pathogens (e.g., bacteria that attack the plant), animals consuming the plant, and environmental conditions (e.g., availability of water). Upon receiving pheromone molecules from a sender plant, the receiver plant performs a corresponding behavior (such as producing chemicals to repel bacteria).

Some passive transport systems use impulses to achieve frequent and fast communication. As a result of the quick increase and decrease of the information molecule concentration in the environment, the information molecule concentration appears as a directed impulse

that propagates away from the sender nanomachine. For instance, some epithelial (skin) cells produce impulses of calcium ions (Ca^{2+}) for intercellular communication. The endoplasmic reticulum (ER) in a cell gathers and stores calcium ions, and when the sender cell is stimulated (e.g., by a physical stimulus), it releases the stored calcium ions from the ER and the calcium diffuses to adjacent cells through cell-cell junction channels. The diffused calcium in turn stimulates the adjacent cells, causing a chain reaction of calcium stimulation. Shortly after being stimulated and releasing calcium, a cell pumps calcium within the cell back into the ER and suppresses further stimulation, thus creating a short impulse of calcium through the cell. Because the communication propagates in a short impulse of calcium concentration, the sender cell can communicate at a higher frequency. Neurons similarly produce ion impulses that propagate over the length of the neuron.

Active Transport-Based Molecular Communications in Biological Systems

Examples of active transport of information molecules in biological systems include motor-based transport of molecules within a biological cell in intracellular communication and transfer of DNA through bacteria conjugation described in the section on “Biological Nanomachines in Biological Systems.” Active transport of information molecules provides a communication mechanism to transport large molecules to specific locations in a biological system. It is directional, because transport molecules move along guide molecules. Active transport can move large information molecules over relatively longer distances (up to meters in length) as compared with diffusion-based passive transport. Large information molecules and vesicles diffuse poorly in passive transport because of their size; on the other hand, active transport consumes chemical energy and generates sufficient force to directionally transport large information molecules (Bullock et al. 2005).

Active transport in biological systems provides a communication mechanism with a high degree of reliability even when the number of information molecules to transport is small. Because the transport of information molecules in active transport is directional, the probability of information molecules reaching the receiver nanomachine is higher than when using passive transport, and thus active transport requires fewer information molecules to perform communication.

Active transport requires significant communication infrastructure to produce and maintain the transport, guide, and interface molecules (e.g., molecular motors, microtubules filaments, and vesicles). Transport molecules must consume a regular supply of energy to overcome the chemical interactions between the information molecule and molecules in the environment.

Molecular Communication Networks in Biological Systems

Biological cells form into larger-scale organisms with a variety of functions. Thus, the biological system requires

an entire network of molecular communications to coordinate among the many cells. The functionality of a network of molecular communication is necessary to coordinate self-organization of the cells during a developmental phase and also to coordinate cells in the complete organism.

In order for a single cell (e.g., an egg) to develop into a large-scale multicellular organism (e.g., a mouse), cells use molecular communication. For instance, cells in a developing embryo (Forgacs and Newman 2005) use molecular communication and develop into specific shapes and structures through the cellular morphogenesis process. During the cellular morphogenesis process, a single cell replicates into multiple cells that self-organize into different organs (e.g., a cell differentiates into a skin cell or a neuron) with specific shapes and locations in the organism (e.g., a group of cells forms the shape of a finger or the shape of a wrist). Cells in the developing embryo diffuse molecular signals for the purposes of establishing gradients in the environment, synchronizing cells, and identifying the role of each cell. Sender and receiver nanomachines (e.g., cells in the finger and wrist) also use molecular signals to control the relative position of cells (e.g., to grow the hand at the end of the wrist), the amount of growth (e.g., to determine the length of each finger), and the pattern of growth (e.g., to grow five fingers). A sender nanomachine (or a group of sender nanomachines) controls the number of information molecules produced (e.g., in order to create a high enough concentration of specific information molecules to cause cells to differentiate into a finger) and the timing of molecule release (e.g., releasing information molecules for a certain duration to determine the length of the finger).

Molecular communication also provides a mechanism for nanomachines to communicate and coordinate within a developed large-scale functional biological system. After a single cell develops into a multicellular organism, the cells in the multicellular organism use a network of molecular signals to control many complex signaling pathways. For instance, cells use glucose molecules as molecular signals to regulate various metabolic pathways. From the high-level architectural view, the metabolite molecules form a molecule interaction graph that consists of a set of nodes and edges. The nodes of the graph represent metabolites (i.e., information molecules) and the edges of the graph represent chemical pathways to convert one metabolite into another. Cells synthesize glucose molecules from the many different forms of chemical energy available to the cells (e.g., various metabolites) and the cells convert the glucose molecules into a large number of different molecules such as amino acids, sugars, and nucleotides (Broder et al. 200; Csete and Doyle 2004). The graph of the metabolites reveals that it is simple to add a new energy source, since it is necessary only to add a new edge from the energy source to the glucose molecule and the edges (i.e., chemical reactions) from the glucose molecule to the receiver nanomachines do not require changes. The network structure identified in the graph of metabolites may serve as a foundation for molecular communication system design.

ENGINEERING OF MOLECULAR COMMUNICATION

Observations of biological systems provide a starting point for understanding nanomachines, processes in passive and active transport in molecular communication, and how to organize molecular communication systems. It has now become possible to artificially engineer nanomachines and molecular communication between nanomachines to produce systems of nanomachines. One approach for engineering molecular communication is extending the existing molecular communication in biological systems described in the section on "Observations of Molecular Communication in Biological Systems." Accordingly, many engineered molecular communications use or modify components of molecular communication from biological systems.

Research in engineering molecular communication consists of engineering nanomachines (e.g., sender nanomachines, receiver nanomachines, information molecules) and engineering passive and active transport mechanisms for information molecules. Empirical research also exists to demonstrate the feasibility of, to observe the characteristics of, and to fine-tune engineered nanomachines and molecular communication. Research also exists to create both mathematical and simulation models from experimental observation. These models serve as a basis for predicting properties of larger-scale and complex engineered molecular communication that is experimentally difficult or costly to produce.

Nanomachines

Engineering nanomachines is necessary to introduce new communication functionality and communication signals to use for molecular communication. Sender and receiver nanomachines in engineered molecular communication need new communication functionality such as that to release specific information molecules (at a sender nanomachine), to control the rate of information molecule release (at a sender nanomachine), and to detect specific information molecules (at a receiver nanomachine). There are three classes of approaches for developing nanomachines: they are modifying existing biological nanomachines such as cells and bacteria (e.g., through genetic engineering), producing simplified cell-like structures using biological materials (e.g., through embedding proteins in a vesicle), or designing other chemical reactions that produce logic and communications.

Modified Biological Cells

One of the three classes of approaches to introduce new communication functionality and communication signals to use for molecular communication is to modify existing nanomachines in biological systems through genetic engineering of their DNA. For instance, a new DNA sequence may be added to a bacterium to add a new functionality. One technique to add a new DNA sequence into a bacterium is to synthesize a DNA sequence in the form of a plasmid (a segment of DNA) that encodes the desired functionality and to have the bacterium cell uptake the plasmid. Current DNA synthesis techniques can reliably

produce arbitrary DNA sequences of up to approximately 10,000 base pairs (Baker et al. 2006). A DNA sequence of 10,000 base pairs is still sufficient to encode a large protein (plus nearby regulator sequences) and produce (e.g., proteins and logic components) useful functionality in a bacterial cell. With the advancement of the technology, it may become possible to artificially synthesize longer DNA sequences and, thus, to increase the ability to introduce new functionality into cells.

In the area of synthetic biology, researchers have demonstrated, through genetic engineering of DNA, creation of bacteria that are capable of performing a simple logic such as an oscillator (Elowitz and Leibler 2000). The bacterium has inserted DNA sequences that cause the bacterium to oscillate the concentration of three protein products (TetR, cI, LacI) over time. The DNA to be inserted into the bacterium was selected so that TetR blocked the promoter sequence of cI, cI blocked the promoter sequence of LacI, and LacI blocked the promoter sequence of TetR. Thus, at time t , TetR is active; cI is blocked; and LacI starts being produced. At time $t + 1$, LacI becomes active; TetR is blocked; and cI starts being produced. The oscillation cycle is dependent on the time for transcribing DNA and the time for the cI, LacI, or TetR to block a promoter sequence; the oscillation, therefore, is slow—on the order of tens of minutes.

Using cells (such as bacteria) as a sender nanomachine has several drawbacks. For instance, some applications may require inserting a DNA sequence into bacteria for new functionality in addition to the oscillator; however, selecting the new DNA sequence may be difficult, since using the molecules TetR, LacI, and cI or similar molecules will influence the activity of the bacteria to act as an oscillator. Another drawback results from cells controlling molecular communication by regulating DNA. Regulating DNA introduces significant processing delay (minutes to hours), since specific DNA sites must be regulated by information molecules (e.g., TetR, cI, or LacI), and the DNA must be transcribed (copied to mRNA) and translated (converted to a protein sequence) to perform chemical reactions for the production of information molecules (e.g., to produce proteins that lead to TetR, cI, or LacI). Also, the environment must be maintained at conditions in which biological cells will survive (e.g., at around 37°C), thus limiting the applicability for molecular communication.

Engineering Cells Using Biological Materials

One of the three classes of approaches to introduce new communication functionality and communication signals to use for molecular communication is to produce simplified cell-like structures using biological materials (e.g., through embedding of proteins in a vesicle). Simplification of biological systems (e.g., cells) may lead to components that are easier to engineer.

One example of the approach of simplification is to start with a lipid bilayer and then add functionality as necessary (Kikuchi, Ikeda, and Hashizume 2004). The lipid bilayer is similar to the membrane that encloses a cell. The lipid bilayer forms into a vesicle (a spherical lipid bilayer), and functional proteins (e.g., a receptor) are either embedded into the vesicle (Figure 4) or are

Figure 4: A functionality-embedded lipid bilayer: This is a highly simplified system of an artificial receptor and enzyme components inserted into a lipid bilayer (Kikuchi et al. 2004; Sasaki et al. 2006). An artificial receptor reacts to a substrate, which leads to the formation of a product.

captured inside the vesicle. Kikuchi et al. (2004) successfully embedded an active receptor and enzyme into a lipid bilayer, producing sender and receiver functionalities. By restricting the number of functionalities that are embedded in the vesicle, it is not necessary to consider the various complex processes (e.g., other metabolic pathways in the cell and processes to maintain the structure of the cell) occurring in a natural biological nanomachine. For instance, it is possible to select chemicals to cause the vesicles to form tubular projections to connect the vesicles without having the complete set of chemical processes from a normal cell (Akiyoshi et al. 2003; Nomura et al. 2005). Note that, on the other hand, the engineered vesicle is more dependent on a supply of metabolite molecules from outside the vesicle.

Engineering of Nanomachines Using Chemical Reactions

One of the three classes of approaches to engineer new nanomachines is to use other molecules, such as DNA sequences or other non-DNA molecules, rather than to use cells or cell-like structures. Nanomachines produced from other molecules are able to perform logic functions, form structures, or provide a method of encryption.

DNA sequences can be selected to produce useful logic and communication functionality in a nanomachine. Note that the DNA sequences exist freely in solution and are not contained inside a cell. For instance, a DNA sequence can act as a receiver of information molecules (e.g., proteins or other DNA sequences). The information molecule binds to the DNA sequence and/or changes the sequence of base pairs in the DNA. The chemical reactions using DNA sequences are highly specific, since only certain molecules (e.g., specific proteins or other DNA sequences) will recognize and react to a specific DNA sequence. The specificity of chemical reactions involving DNA sequences allows them to perform logic functions (e.g., when DNA sequences A and B are both present, DNA with structure C will form) (Benenson et al. 2004). Such DNA logic functions can select DNA sequences that represent solutions to NP-complete (nondeterministic polynomial time)

problems in a massively parallel fashion (Adleman 1994; Winfree et al. 1998); however, scalability of searching for a specific DNA sequence for NP-complete problems is currently limited (Cox, Cohen, and Ellington 1999).

The specificity of chemical reactions involving DNA sequences also applies to forming three-dimensional structures. Nanomachines may require a three-dimensional shape to position molecules in an environment for a larger-scale molecular communication device. One approach to form three-dimensional structures is to bind single-stranded DNA sequences together (DNA naturally occurs in a double-stranded state, which is formed from two complementary single-stranded DNA sequences). A single-stranded DNA sequence contains exposed sequences that readily bind to a single-stranded DNA sequence that contains a complementary sequence. A single-stranded DNA sequence can also bind to itself and fold itself into a certain shape (e.g., to form a hairpin structure) if a part of a single-stranded DNA sequence is complementary to another part of its DNA sequence. If pieces of a single-stranded DNA sequence remain exposed after binding to a complementary sequence, other single-stranded DNA can subsequently bind to the exposed pieces of the single-stranded DNA. Thus, the single-stranded DNA can repeatedly bind to more single-stranded DNA to form larger structures (Sakamoto et al. 2000; Mao et al. 2000). Structures created by a single-stranded DNA sequence through binding may be complex and may provide a potential scaffold for precise binding of other single-stranded DNA sequences onto the scaffold.

The specificity of chemical reactions involving DNA sequences also applies to performing encryption of information into DNA sequences (Gehani et al. 2004). For instance, information may be encoded onto a sequence of DNA, and the information-encoded DNA sequence may bind another DNA sequence that represents an address tag for the information-encoded DNA sequence. The information-encoded DNA sequence with the address tag is then mixed into a large number of other random DNA sequences and can be retrieved only by using a DNA sequence that chemically binds to the tag. Security is important in communication, and since nanomachines may be too simple to perform complex security functions, approaches such as this may provide techniques for security in molecular communication.

In addition to using DNA sequences, non-DNA molecules (artificially designed molecules using chemistry techniques) may be used to introduce new communication functionality and communication signals for molecular communication. Artificially designed molecules have been identified with chemical characteristics that also receive information molecules and perform useful logic functions. If the artificially designed molecules are integrated to form a system of chemical reactions, more complex logic functions may be possible (Zauner and Conrad 2001); however, large-scale integration of artificially designed molecules remains to be experimentally demonstrated.

Passive Transport

Research in engineering molecular communication includes developing passive and active transport mechanisms for propagating information molecules through the

environment. This section describes passive transport mechanisms. Later sections describe passive transport by which information molecules propagate using free diffusion through the environment and another type of passive transport by which information molecules propagate in a wave-like impulse.

Passive Transport Using Free Diffusion

The simplest method for propagating information molecules through the environment is passive transport of information molecules using free diffusion. Passive transport using free diffusion represents a broadcast communication to all receiver nanomachines in range; however, the concentration of information molecules released in the environment generally decreases as the distance from the sender increases (e.g., it is inversely proportional to the square or cube of the distance from the sender). The concentration of information molecules, thus, may be undetectable by receivers if they are distant from the sender.

In free diffusion-based passive transport, it is beneficial to have mechanisms for the sender nanomachine to address a specific receiver nanomachine (or a set of specific receiver nanomachines), since communication is inherently a broadcast with free diffusion. In free diffusion-based passive transport, a receiver nanomachine may have receptors that are specific and that respond only when a certain type of information molecule is present in a high enough concentration (Weiss and Knight 2000; Gerchman and Weiss 2004). Thus, the sender nanomachine may select the receiver nanomachine by sending the information molecules that cause a response at the receptors of the desired receiver nanomachine. The sender nanomachine may also set the concentration of information molecules (by adjusting the number of information molecules to transmit) so that only nearby receiver nanomachines with the specific receptor are capable of responding, and distant receivers

do not respond. For instance, an engineered bacterium produces VAI (*Vibrio fischeri* autoinducer) information molecules, and the VAI information molecules diffuse through the environment and bind to VAI-specific receptors (i.e., a specific DNA sequence that binds VAI) in a receiver bacterium (Weiss and Knight 2000). The receiver bacterium decodes the VAI information molecule into the production of GFP (green fluorescent protein) (Haraguchi, Koujin, and Hiraoka 2000). The VAI-specific receptor thus acts as an address tag of the receiver bacterium. With a sufficiently high concentration of information molecules (VAI) received at a receiver bacterium, GFP is produced inside the receiver bacterium in large enough amounts for fluorescence to be visible under ultraviolet (UV) light (Figure 5). Note that this addressing is not dynamic, since the sender bacterium must have prior knowledge regarding which information molecules (e.g., VAI) are necessary to contact the receiver bacterium.

Passive Transport Using Impulse-Based Communication

In addition to the free diffusion-based passive transport, an alternative and more complex form of passive transport is possible. This form of passive transport uses additional (non-information) molecules in the environment. These additional molecules in the environment release/generate information molecules (in response to information molecules created by a sender nanomachine) and cause a wave-like impulse of information molecules that propagate through the environment. Examples of such passive transport using impulse-based communication are a BZ (Belousov-Zhabotinsky) reaction and calcium signaling inside a cell and between cells.

The first example of passive transport using impulse-based communication is to use a BZ reaction. A BZ reaction generates an impulse wave of chemical concentrations through nonequilibrium chemical reactions.

Figure 5: Addressing in passive transport using free diffusion. Chemical reactions in a sender bacterium convert a metabolic product into a steroid-like information molecule (e.g., VAI). The VAI molecules freely diffuse in the environment and reach a receiver bacterium, which contains a receptor specific to VAI. Upon arrival at the receiver bacterium, the VAI molecules bind to the receptor. With some probability, information molecules freely diffuse into a DNA regulation site inside a receiver bacterium and activate DNA, resulting in production of GFP (Weiss and Knight 2000). Receiver bacteria with GFP produce visible fluorescence under UV light. The DNA regulation site represents the address of the receiver bacterium, since other receiver bacteria without an appropriate DNA regulation site (e.g., a DNA sequence that binds to VAI) will not respond to the information molecule.

Figure 6: In a BZ reaction, the chemical concentration oscillates and generates a visible impulse wave of chemical reactions. This figure illustrates an impulse wave of chemical reactions in a BZ reaction originating from a single point and emanating in an expanding circular pattern. The actual information molecules from the origin point do not propagate with the wave, and only the impulse wave propagates.

A BZ reaction caused by a specific set of chemicals [e.g., HBrO_2 , Br^- , ferriin (blue), and ferroin (red)] generates an impulse wave that spatially and temporally oscillates (Figure 6). The oscillation in a BZ reaction is caused by continuous reactions among the set of chemicals, and it may be modeled as a positive and negative feedback system.

In a BZ reaction, the chemical bromous acid (HBrO_2) (i.e., the information molecule) increases its concentration through an autocatalytic reaction. The increase in HBrO_2 , in turn, promotes nearby ferroin (red) to convert to ferriin (blue) (Adamatzky 2004; Ichino et al. 2003). This positive feedback increases ferriin (blue) in the environment. When the concentration of ferriin (blue) becomes very high in the environment, ferriin (blue) starts to convert back to ferroin (red). When ferriin (blue) converts to ferroin (red), it produces bromide ion Br^- , which in turn suppresses the autocatalytic reaction to produce HBrO_2 . This suppression of the autocatalytic reaction and natural decay of HBrO_2 in the environment form a negative feedback and result in reduction of the concentration of HBrO_2 in the environment. This positive and negative feedback generates an impulse wave that propagates in the environment.

Through the positive and negative feedback described above, the BZ reaction continuously generates impulse waves that propagate in the environment. Note that in a BZ reaction the chemicals [e.g., HBrO_2 , Br^- , ferriin (blue) and ferroin (red)] that generate an impulse wave do not actually propagate with the impulse wave, and only the impulse wave propagates.

Nanomachines may use a BZ reaction to perform logic functions in a manner similar to the logic in electrical computer components. For instance, an AND gate may result from two input BZ reaction waves colliding and producing an output wave through a chemical reaction of the two colliding input BZ reaction waves. Synchronization between the two input waves may be necessary to generate an output wave at a desired location, introducing a difficulty in design. However, implementing a logic

gate using BZ reactions may lead to novel devices such as a detector for the distance to a wave source (Gorecki et al. 2005) or a detector for the direction to the wave source (Nagahara, Ichino, and Yoshikawa 2004).

The second example of passive transport using impulse-based communication is to use calcium signaling inside a biological cell (i.e., intracellular calcium signaling). Inside a cell, a calcium store (e.g., ER) has calcium channels (e.g., ryanodine receptor calcium channels). The calcium channels release calcium signals from the calcium store when calcium signals activate the calcium channels. Released calcium signals diffuse inside a cell and activate nearby calcium channels, which, in turn, release calcium signals from their calcium stores. The concentration of calcium inside a cell increases through this positive feedback. When the concentration of calcium becomes high, the cell uses various calcium pumps to remove calcium signals from the cell. This acts as a negative feedback. Similar to the BZ reaction, the positive and negative feedback produce a propagating impulse wave of calcium signals inside a cell. An impulse wave of calcium signals may be used to perform logic operations (Hentschel, Pencea, and Fine 2004). For instance, an AND gate may be composed of two calcium channels acting as inputs to and one calcium channel acting as an output from the AND gate (Figure 7). Each of these calcium channels is associated with a calcium store and releases calcium signals upon activation by calcium signals. In this AND gate, the output calcium channel releases calcium signals from the calcium store that it is associated with only when two input calcium channels are active, releasing calcium signals from their associated calcium stores.

Yet another example of passive transport using impulse-based communication is to use calcium signaling between biological cells (i.e., intercellular calcium signaling). Multiple cells are coupled through cell-cell channels called gap-junction channels. Gap-junction channels allow passage of small molecules between cells, and a calcium impulse wave generated inside a cell (as described in the previous paragraph) propagates through gap-junction channels to its adjacent cell. Similar to the AND gate design based on intracellular calcium signaling described in the previous paragraph, impulse waves of calcium signals between cells may be used to perform logic operations. For instance, cells may be placed on a glass surface to create a desired pattern of cells (Ostuni et al. 2000), and a logic gate may be designed in a manner similar to that described in the previous paragraph using impulse waves of calcium signals between cells (Figure 8) (Nakano et al. 2005). In addition, since it is possible to dynamically control and modify permeability and gating properties of gap-junction channels, it may be feasible to design a more complex logic gate using calcium impulse waves propagating through gap-junction channels between cells placed on a glass surface.

Using impulse waves of calcium signals inside a cell and between cells for performing logic operations may lead to the development of biocomputing devices that are highly compatible with biological systems. Note, however, that such devices may be slower to operate and more difficult to control than those developed using currently available electrical technology.

Figure 7: A design of an AND gate based on impulse-based passive transport using intracellular calcium signaling: The design shows an AND gate with two inputs (i.e., two impulse waves from calcium channels A and B) and an output (i.e., an impulse wave from calcium channel C). Each of the three calcium channels is associated with a calcium store and releases calcium signals when activated by calcium signals. When activated, calcium channels A and B generate input impulse waves that propagate in the environment (as indicated by the dotted circles). Calcium channel C generates an output impulse wave only when receiving impulse waves from both calcium channels A and B. The three calcium channels together, thus, perform as an AND gate.

Figure 8: Design of an AND gate based on impulse-based passive transport using intercellular calcium signaling: The design shows patterned cells collectively acting as a logic gate with two inputs (i.e., two calcium impulse waves from cells A and B) and an output (i.e., a reaction of cell C). Cells A and B generate input calcium impulse waves that propagate through gap-junction channels to cell C. Cell C produces a reaction only when receiving calcium impulse waves from both cells A and B, and, thus, the patterned cells collectively perform as an AND gate.

Active Transport

In active transport, transport molecules propagate information molecules (or interface molecules containing information molecules) along the guide molecules. Active transport consumes energy, and thus, it provides a communication mechanism to transport large molecules (large information molecules or large interface molecules) to specific locations over relatively long distances (up to meters in length) (Ebeling and Schweitzer 2003). It is directional, because transport molecules move along guided molecules. Active transport, however, requires significant communication infrastructure to produce and maintain the transport, guide, and interface molecules (e.g., molecular motors, microtubules, and vesicles). For instance, transport molecules require a regular supply of chemical energy to transport information molecules or interface molecules.

Existing research in engineering active transport systems is experimental and focuses on examining various methods for controlling the propagation (e.g., direction of movement) of molecular motors and developing new methods of self-organizing a communication infrastructure. Determining the locations of molecular communication components (e.g., sender and receiver

nanomachines, guide molecules) in a self-organizing manner, is particularly important in engineering active transport, since the location of molecular communication components may significantly impact the performance of molecular communication. On the other hand, in passive transport, a broadcast of information molecules reduces the need for precise location of molecular communication components.

The following subsections describe two types of active transport, active transport using molecular motors (borrowed from biology) and active transport using DNA walkers (using artificially designed chemical reactions).

Active Transport Using Biological Molecular Motors

One type of active transport is to use molecular motors to transport information molecules or interface molecules containing information molecules. Biological systems include a variety of molecular motors (e.g., kinesin, myosin, cilia, flagella, etc.). Existing research on engineering active transport, however, focuses on only a few types of molecular motors (i.e., kinesin, dynein). Three examples of active transport using molecular motors are molecular motors walking on filaments, filaments

propagating on a patterned surface coated with molecular motors, and biological cells moving through an aqueous solution using molecular motors.

In the first example, engineered active transport uses molecular motors, guide molecules (e.g., microtubule filaments) that self-organize into a network, and molecular motors (e.g., dynein, kinesin) that actively transport information molecules along the guide molecules (Suda et al. 2005; Moore et al. 2006). This first example uses components and processes similar to the active transport mechanisms in biological systems. In biological systems, a network of guide molecules (e.g., actin or microtubule filaments) is created within a cell in a self-organizing manner through dynamic instability (Figure 9) of guide molecules, and molecular motors (such as dynein and kinesin) transport information molecules to specific locations within the cell by walking along a network of guide molecules. Engineering of the self-organization of the filaments can produce simple patterns of filaments (e.g., a star-shaped pattern or a random mesh pattern) (Chakravarty, Howard, and Compton 2004; Enomoto et al. 2006; Hayashi et al. 2006). Through designing self-organization processes of creating filament patterns and through selectively transporting on the designed filament pattern, molecular motors may be guided to desired locations (e.g., desired receiver nanomachine or a desired set of receiver nanomachines). However, the patterns of filaments that are created through engineering self-organization of the filaments are currently simple and limited, since control over self-organization remains difficult.

In the second example of engineered active transport using molecular motors, the arrangement of microtubules and motors is inverted. A surface of a glass is coated with the molecular motor (e.g., kinesin), and the motors push the filaments along the surface. In this arrangement, transport molecules (i.e., the filament) load information molecules at a sender nanomachine and unload the information molecules at a receiver nanomachine (Hess et al. 2003; Hiyama et al. 2004). The direction of filament movement is guided by adding walls (e.g., deposited proteins) onto the glass surface through lithographic techniques.

Figure 9: A microtubule and dynamic instability. A microtubule is a protein polymer consisting of tubulin dimers forming a hollow cylinder. A microtubule grows and shrinks through dynamic instability: the microtubule grows slowly by polymerizing tubulin dimers and stochastically shrinks by depolymerizing tubulin dimers. Tubulin dimers after depolymerization are still available in the environment for microtubule growth.

Figure 10: Rectifying the direction of a filament during active propagation on a patterned glass surface. Filaments move along a glass surface coated with molecular motors: (A) Patterned walls on the surface guide filament molecules. (B) When the filament moves in the direction of the arrow, movement direction is preserved. (C) When the filament moves against the direction of the arrow, the walls cause the filament to reverse its direction into the direction of the arrow.

Various patterns may be generated that gather filaments toward a receiver nanomachine. For instance, an arrow-shaped wall pattern acts a directional rectifier (Figure 10) to ensure that filaments propagate in a single direction (e.g., only clockwise) by rectifying filaments that are propagating opposite the arrowhead direction (Hiratsuka et al. 2001).

In the third example of engineered active transport using molecular motors, a transport molecule itself is a nanomachine using molecular motors to move itself toward a receiver nanomachine along chemical gradients in the environment. This third example uses components and processes similar to self-propulsion of single-cell organisms (e.g., a bacterium) through an aqueous solution. In biological systems, a bacterium (i.e., a transport nanomachine) uses cilia or flagella (molecular motors that generate propeller-like forces) to move itself along chemical gradients toward favorable conditions (e.g., food source, light) and away from unfavorable conditions (e.g., harmful chemicals, light). The receiver nanomachine may generate guide molecules (similar to a gradient of a food source or pheromone in the environment in the bacterium example) to indicate where the receiver nanomachine is and to influence the direction in which the transport nanomachine moves through the environment. The transport nanomachine does not require preestablished filament networks, since guide molecules emitted by a receiver nanomachine randomly diffuse to form the chemical gradient around the receiver nanomachine. For instance, the pseudopodia of a cell (projections from a cell) can form complex shapes such as a structure that links the entrance and exit of a maze (Nakagaki, Yamada, and Tóth 2000). The pseudopodia form the structure by growing toward a chemical gradient of food originating from both the entrance and the exit of the maze. Active transport using pseudopodia is robust, since the pseudopodia adapt to match the shape of the maze.

Active Transport Using DNA Walkers

Another type of active transport uses DNA walkers that actively transport information molecules. A DNA walker is an artificially designed DNA sequence that walks along a DNA track (Shin and Pierce 2004; Yin et al. 2004).

Figure 11: A DNA walker progressing along a DNA track from left to right. The DNA walker has two legs, W1 and W2 (i.e., the two single-stranded DNA sequences), and three branches, T1, T2, and T3 (i.e., the three single-stranded DNA sequences protruding from the DNA track). The DNA walker progresses by attaching to and detaching from the DNA track. First, DNA sequence A1 is partially complementary to both W1 and T1, and when A1 is introduced in the environment, A1 forms a bridge to bind W1 to T1. Second, DNA sequence A2 is partially complementary to both W2 and T2, and when A2 is introduced in the environment, A2 forms a bridge to bind W2 to T2. Third, DNA sequence D1 is perfectly complementary to A1, and when D1 is introduced in the environment, D1 detaches W1 from T1, freeing leg W1 from the DNA track. An additional walker step is possible by introducing a DNA sequence that can bridge from W1 to T3.

Figure 11 illustrates a DNA walker. In the example shown in Figure 11, the DNA walker has two single-stranded DNA sequences (i.e., W1, W2), called “legs,” to walk along the DNA track. The DNA track has three branches of single-stranded DNA sequences (i.e., T1, T2, and T3) protruding from the DNA track. A series of DNA hybridization and dehybridization allows one leg of the DNA walker to bind to the next branch of the DNA track, while keeping the other leg bound to a branch, so that the DNA walker progresses without detaching from the DNA track. The DNA track is, thus, a guide molecule that determines the position of each step of the DNA walker. Similar to molecular motors, the DNA walker may transport a cargo (i.e., information molecules or interface molecules containing information molecules) along the DNA track. Alternatively, the DNA walker itself may represent information (e.g., a DNA sequence representing some information).

DNA walkers have several properties that are different from molecular motors described in the section on “Active Transport Using Biological Molecular Motors.” Binding between DNA sequences is strong, and thus, active transport using DNA walkers is likely to be highly reliable and may require few information molecules to achieve communication. On the other hand, binding of protein molecular motors is weak, and molecular motors may stochastically unbind at any step of the walk; thus, a large number of molecular motors may be necessary to achieve successful communication. In addition, DNA walkers allow precise control over each step of movement. On the other hand, molecular motors walk stochastically; thus, it is difficult to precisely control the walking. Although existing research on DNA walkers has only demonstrated limited walking capability,

continued research on DNA walkers may provide a scaffold for precise movement of DNA walkers on a grid of DNA tracks.

ENGINEERING OF MOLECULAR COMMUNICATION NETWORKS

As described in the section above on “Engineering of Molecular Communication,” the existing research in molecular communication focuses on building components for molecular communication (e.g., nanomachines that have new communication functionality and communication signals, active and passive transport that transport information molecules or interface molecules containing information molecules). Such components, however, must work together to produce useful molecular communication (Drexler 1999; Zauner and Conrad 2001). An entire system of molecular communication (referred to as a “molecular communication network”) will allow nanomachines to communicate not only through exchanging a low-level signal at the physical layer but also through exchanging information with higher-level meaning so that groups of nanomachines are able to perform complex and meaningful functions.

Existing research in creating an entire system of molecular communication (i.e., existing research toward creating a molecular communication network) includes research on providing a generic interface for interacting with a biological system, creating an addressing mechanism to enhance communications, and engineering simple molecular communication networks. In addition, research in asynchronous systems may provide mechanisms to handle properties of stochasticity and

large propagation delay in molecular communication and provide methods to design a molecular communication network. Continued research into techniques in biology and nanotechnology, and computer science, may lead to some of the applications described in the section on “Applications.”

Components for a Molecular Communication Network: Communication Interface

A communication interface provides a generic abstraction for communication that is reused by a variety of communication mechanisms. In molecular communication, a generic and abstract communication interface allows sender and receiver nanomachines to transport a variety of molecules using the same communication mechanism (Chen, Torchilin, and Langer 1996). Creating a generic and abstract communication interface is important in a molecular communication network, since, with such a communication interface, a communication component is designed without requiring details of other communication components.

One example of a generic and abstract communication interface is found in drug delivery. In drug delivery, varieties of drugs are encapsulated in nanoscale capsules and target some location in the human body (Figure 12). Targeting molecules embedded in the nanoscale capsule bind to a specific receptor embedded in the target location inside the human body. The location of the receptor molecule in the human body thus determines the eventual location of the nanoscale capsules. With this interface, drug targeting mechanisms do not rely on characteristics of the drug (i.e., the information molecule) being transported. Nanoscale capsules act as a generic and abstract communication interface. The interface molecules allow any type of information molecule to concentrate at the correct location, which reduces the amount of drug necessary for results, and thus reduces side effects from drugs reaching undesired locations. The nanoscale capsule also protects information molecules from environmental noise and prevents the information molecules from chemically reacting with molecules outside the interface during the propagation.

Figure 12: Drug delivery using a dendrimer communication interface (Sakthivel and Florence, n.d.). A dendrimer is a branched molecule with drugs embedded in the dendrimer. The dendrimer has targeting molecules on its surface. The receiver cell has a receptor that recognizes the targeting molecule and captures the dendrimer, and the drug is released at the target receiver cell. Alternatively, quorum-sensing mechanisms may apply at the target location to synchronize release of drugs at the target location (Weiss and Knight 2000).

Components for a Molecular Communication Network: Addressing Mechanism

One important feature in communication is the ability to send information to a specific receiver. In molecular communication, an addressing mechanism allows a sender nanomachine to specify the receiver nanomachine independent of the type of information molecules used. With a generic addressing mechanism, the sender nanomachine would have a generic abstraction for specifying receiver nanomachines. In diffusion-based communication in biological systems, a receiver nanomachine is addressed according to which information molecule is being used (see section on “Passive Transport-Based Molecular Communications in Biological Systems”). On the other hand, a molecular communication system using a generic addressing mechanism is more flexible and imposes fewer constraints on which information molecules are used in molecular communication.

One approach for a generic addressing mechanism is using DNA sequences (Hiyama et al. 2005). In the addressing mechanism investigated, the information molecule includes a single-stranded DNA with a sequence that specifies the address of a receiver nanomachine. The receiver nanomachine has an address DNA that is complementary to and thus binds to the single-stranded DNA on the information molecule. Using DNA sequences in addressing provides a method for generating a large number of addresses, since DNA sequences may be arbitrarily produced (with existing technology, DNA up to 10,000 base pairs in length) and binding of DNA sequence is understood (as evidenced by construction of various shapes from designed DNA sequences). Adding an addressing mechanism to molecular communication would allow the creation of more complex molecular communication networks.

Techniques to Create a Molecular Communication Network

Various approaches to create a molecular communication network have come from engineering simple molecular communication networks. Some approaches include: (1) creating standard techniques and standard communication components to develop a molecular communication network, (2) techniques to automatically predict chemical reactions and undesired chemical interactions among communication components, (3) techniques to modify the design of a communication network, and (4) techniques to position nanomachines and communication components.

Creating standard techniques and standard communication components to develop a molecular communication network may improve the ability to successfully design and create a molecular communication network. In computer engineering, new hardware components (e.g., an electric circuit) are integrated into a standardized catalog so that developers can quickly identify and use existing hardware components. In synthetic biology, it is envisioned that computing components that are made of biological materials are specified and cataloged in a manner similar to the circuit design used in

engineering (Baker et al. 2006; MIT Registry 2007). Computing systems with several computing components (e.g., logic gates) made of biological materials have been demonstrated (Nitta and Suyama 2004). Having standard techniques and standard communication components may lead to ease in designing a molecular communication network, similar to standardization of protocols in electronic computer networks.

Techniques to automatically predict chemical reactions and undesired chemical interactions among communication components improve the ability to develop new molecular communication networks. In existing research, reengineered chemical pathways in bacteria produce antimalarial drugs (Martin et al. 2003; Ro et al. 2006); however, such procedures are manual, with a high degree of trial and error. Creating a computing system made of biological materials is complex, since computing components perform chemical reactions, and various computing components may interfere with each other, creating undesired chemical interactions among computing components. Existing techniques to automatically predict chemical reactions and undesired chemical interactions are limited. For instance, techniques from drug development, such as massively parallel assays, reduce the time to test for some undesired chemical interactions (i.e., drug side effects); however, such techniques do not provide conclusive results regarding potential drug interactions. Similar to creating a computing system from computing components made of biological materials, techniques to automatically predict chemical reactions and undesired chemical interactions among communication components are required to create an entire system of molecular communication (a molecular communication network) in which various components of molecular communication work together (e.g., nanomachines that have new communication functionality, active and passive transport molecules that transport information molecules, and interface molecules containing information molecules).

Techniques to modify the design of the communication network improve the ability to improve the design of existing molecular communication networks. Materials from biological systems may be modified and used in creating various components of molecular communication and a molecular communication network. Modifying such materials remains difficult. For instance, cells from biological systems remain difficult to modify, since the DNA and its interactions in biological systems are complex and not fully understood. (For instance, DNA code overlaps so that modification of one base pair in a DNA sequence can change the sequence of two proteins.) One possible approach for modifying and engineering the pathway of proteins is to apply genetic algorithms to select combinations of proteins that produce desired features; however, achieving the correct design through random processes in the genetic algorithm is time consuming. Another possible approach for producing desired functionality in a cell is to rewrite the DNA sequence of cells into a more human-readable format (Endy 2005). This technique improves the human-readability of DNA interactions by removing DNA that appears unnecessary and by expanding DNA sequences so that no code overlaps. However,

DNA sequences are long (3 billion base pairs in a human), and existing techniques to read and write DNA still limit the ability to reengineer biological cells. Improving the ability to modify the DNA of biological cells will improve the ability to add new or remove existing communication functionality from components of molecular communication and from a molecular communication network.

Techniques to position nanomachines and communication components provide an additional technique to increase the functionality of a molecular communication network. If nanomachines are at precise locations on a glass surface, the nanomachines can perform addressing according to distance (by the passive transport using free diffusion, as discussed above). One scalable technique is to use masking techniques from computer circuit design to form cells into a complex pattern on a surface. In amorphous computing, different types of cells are spatially arranged on a surface to produce multiple logic gates (Abelson et al. 1999). In amorphous computing, a group of cells of the same type forms a single logic gate with the same functionality. Multiple groups of cells connect through molecular communication and form a circuit of connected logic gates. Lithography (or another photo techniques) is applied to produce a desired pattern of chemical receptors on a glass surface for placement of cells. Different types of cells recognize and bind to a specific type of chemical receptor on the surface, and thus form the desired pattern of cells (i.e., to form multiple logic gates) on a surface (Healy, Lom, and Hockberger 1994). Another technique to form cells into a complex pattern on a surface is to use a single type of biological cells that differentiates into a type of cell after the cell receives an external signal (e.g., light with a specific wavelength). As a step toward such a technique, existing research has demonstrated genetically modified cells that absorb light and change activity (i.e., produce GFP resulting in a photograph-like image) in response to the absorption of light. Extension of existing research may eventually lead to simple top-down engineering of complex cell patterns (rather than the bottom-up self-organizing creation of patterns in morphogenesis). These techniques produce patterns similar to patterns in electronic circuit design, and thus, techniques from electronic circuit design may extend to aid in producing a wide range of molecular communication devices. These techniques, however, may need to consider that cells may randomly migrate to different locations on a surface or may stochastically respond to external control signals.

Asynchronous Communication in a Molecular Communication Network

Concepts and techniques from asynchronous computing systems may provide guidelines for the design of an entire system of molecular communication (a molecular communication network) in which components of molecular communication work together. Asynchronous computing systems address timing and coordination issues that also appear in a molecular communication network.

Cellular automata, one type of asynchronous computing systems, provide a discrete-time model of the

interactions occurring in spatially distributed components of a computing system, and it may apply to describing and understanding the interactions among various components of molecular communication (such as sender and receiver nanomachines). In cellular automata, autonomous “cells” are located on an N-dimensional grid. Note that a cell in cellular automata is not a biological cell and refers to a functional unit that performs simple logic action including a cell changing its state, a cell replicating into an empty adjacent cell (causing the adjacent cell to have the same state as the cell), or exchanging resources among neighboring cells. At discrete time intervals, each cell considers information from adjacent cells and follows predefined logic functions to decide what action it takes. Cellular automata may provide some intuition regarding pattern formation in the morphogenesis of biological systems (e.g., transmitting waves of information or modeling of limb formation). Cellular automata may also provide insights into the design of some simple logic that achieves given patterns. In applying cellular automata to design of a molecular communication network, however, it is necessary to consider the stochastic nature of various components of a molecular communication network: their stochastic nature may disrupt the ability of adjacent cells to transmit information molecules in a correct and timely manner.

Asynchronous computing systems require no synchronizing clocks (Davis and Nowick 1997). Developing a synchronizing clock for molecular communication is difficult, since the sender and receiver nanomachines need to integrate information from both information molecules and the synchronizing signal. In molecular communication, an asynchronous architecture may allow a sender nanomachine to transmit an information molecule to the receiver nanomachine and the receiver nanomachine to respond when it is ready for the next information molecule. This form of communication applying feedback from the receiver nanomachine to the sender nanomachine requires no synchronizing clocks. Molecular communication networks will likely benefit from asynchronous communication to address issues of probabilistic delays in molecular communication and biological systems.

CONCLUSION

Molecular communication first began as observations of molecular-based communication between biological entities (e.g., individual bacteria cells). Initial research of engineering molecular communication began as development of drugs and their delivery; however, early research in drug development and delivery only modified the activity of signal pathways that already existed in a receiver cell. Molecular communication, since then, has progressed to reengineering molecular communication pathways inside a receiver cell so that other, new drugs can modify the activity of the receiver cell. It has also progressed to consider molecular communication components that are not found in biological systems. The expansion of components available for molecular communication may find applicability in a number of biological systems or in harsh environments where biological components do not function well.

Molecular communication is still an emerging field. Existing research in molecular communication considers both the lowest layer of communication (namely, how information molecules are exchanged between a sender and a receiver nanomachine) and integration of multiple nanomachine devices. There is little research done to address higher-layer issues. The following research issues still need to be addressed: develop a feedback mechanism between sender and receiver nanomachines; route information molecules over a complicated topology of guide molecules (in case of active transport); and encode information onto information molecules in a generalized manner that receiver nanomachines understand and that creates a desired chemical reaction at the receiver nanomachine.

Although research in molecular communication is in its infancy and has only reproduced functionality already available either in biological systems or through other existing technologies (e.g., logic gates, light-sensitive surfaces, mechanisms to transport molecules using molecular motors), continuing research in molecular communication will lead to a molecular communication network in which various components of molecular communication work together to provide full communication functionality and enable new and novel applications that increase interaction with biological systems. Molecular communication also poses some concern about impacting ecological systems and introducing potentially harmful artificial systems (Check 2006). The field of molecular communication is progressing toward standardizing techniques for creating molecular communication components and may eventually lead to disciplined design of nanoscale communication systems that addresses concerns about safety and ecology.

GLOSSARY

ATP (Adenosine 5'-Triphosphate): Cells use ATP as an energy source in various biological cellular processes, including metabolic activities, motility, and cell division.

Axon: A distinctive part of a nerve cell or neuron that propagates electrical impulses. An axon is typically 1 μm in diameter, and it may extend from 1 mm to 1 m in length.

Cell: The basic functional and structural unit of all living organisms, from unicellular organisms such as bacteria to multicellular organisms such as plants and animals. Cells are classified as prokaryotic and eukaryotic. A eukaryotic cell contains a nucleus and is relatively large (1–100 μm). A eukaryotic cell contains organelles to perform a variety of functions such as a nucleus to store DNA molecules, mitochondria to produce ATP, chloroplasts to absorb light energy, and vacuoles for storage/structural support. A prokaryotic cell has a simple structure without a nucleus and is relatively small in size (1–10 μm).

DNA (Deoxyribonucleic Acid): A DNA molecule is a sequence of nucleic acids that stores genetic information of a living organism. A DNA molecule contains information necessary to construct various cellular components such as proteins. Specific proteins and

molecules regulate the activity of segments of a DNA sequence.

Drug Delivery System: The goal of a drug delivery system is to deliver a controlled amount of pharmaceutical compounds to a target site of a body. Existing research in drug delivery systems includes design and development of drugs that are transported to a target site of a body and become activated only at the target site.

ER (Endoplasmic Reticulum): A cellular organelle found in all eukaryotic cells. ER has a membrane structure in which protein translation, folding, and transport occur.

Filament: A long chain of proteins found in a cell. Examples include microtubules and actin filaments.

Gap-Junction Channel: A cell-cell channel connecting two adjacent cells. Gap junction channels allow passage of small molecules (normally smaller than 1000 Da) between cells, enabling coordination and communication between cells.

GFP (Green Fluorescent Protein): A fluorescent protein produced by the jellyfish *Aequorea victoria*. GFP emits green fluorescence when exposed to blue light. In molecular and cell biology studies, GFP is often used as a marker protein for observing expression and dynamics of proteins of interest.

Liposome: A vesicle formed of a spherical lipid bilayer membrane.

Molecular Motor: A protein or protein complex that transforms chemical energy (i.e., ATP) into mechanical work at the molecular scale. The examples of molecular motors include myosins, kinesins, and dyneins.

Nanomachine: Nanomachines include naturally existing biological systems (e.g., cells), genetically altered biological systems, artificially synthesized devices, and hybrid biological-artificial systems, whose sizes are all measured in nanometers or micrometers.

Neuron: A nerve cell that plays a major role in transmitting electrical impulses within a nervous system.

Protein: An organic compound made of a linear chain of amino acids. Each protein or complex of proteins provides some functions such as regulating gene expression and sensing the environment.

Receptor: A protein complex located on a cell membrane or membranes of intracellular organelles such as the nucleus. Receptors react to molecules and activate signaling pathways that initiate cellular responses.
